The Owen Bill.—At the meeting of the New York Academy of Medicine, held on February 7, Dr. Louis Livingston Seaman called attention to the fact that the Owen bill, providing for a reorganization of the Medical Department of the Army, which would confer upon the officers of the Medical Corps the same authority as was possessed by other military officers of equal rank, was one that should receive the attention of the Academy of Medicine and of the entire medical profession. He stated that the Medical Department of the Army had to combat a foe that in all the great wars of history, except the Russo-Japanese War, had caused 80 per cent. of the mortality, and had never had authority to reduce this frightful mortality to a minimum. The passage of the Owen bill would give this authority without in any way interfering with the military operations.

Daily Inspection of Army Hospitals Ordered.—The Secretary of War, under date of February 1, issued orders through the Chief of Staff to all Division and Post Commanders to have an officer of their staff make a daily inspection of hospitals connected with the camp or post and a daily report to the Commanding General, and, in the event of the discovery of any condition needing attention beyond that under his immediate control, to report the fact to the Chief of Staff for the information of the Secretary of War.

Disease Conditions Among Troops in the United States.—A statement issued from the Surgeon General's office shows that the annual admission rate for disease only, per 1000, for all troops in the United States is 1713.6; for the National Guard Camps, 1506.2; for the National Army Camps, 1995, and for the Regulars in Divisions and Departments, 1485.7. The non-effective rate per 1000 on the day this report was made was as follows: All troops, 51.1; National Guard Camps, 49.6; National Army Camps, 55.7, and Regulars, 41.3.

Plea to End Use of Gases in Warfare.—A dispatch from the *Petit Journal* of Paris states that the International Red Cross at a conference in Geneva, on February 6, decided by unanimous vote to appeal to the belligerent powers to suppress the use of asphyxiating and other deleterious gases. Why not ask the Kaiser to refrain from murder and theft and lying and treachery and poisoning wells and baby killing and rape and arson and all the other crimes which his braves are committing daily?

Dr. William Clarence Braistead has been reappointed by the President to serve another term as Surgeon General of the Navy.

Captain Henry James, M. R. C., of New York, who has been stationed at Base Hospital 15 in France since July 1, 1917, has returned to this country on a six months' leave subject to call.

Dr. Henry J. Harp of Sussex, N. J., has been mustered out of service in the Medical Reserve Corps of the Army in compliance with a petition presented to the War Department by the residents of Sussex, pointing out that the community was without adequate medical help and needs his services.

A VITALLY IMPORTANT MEASURE.

THERE is now a bill before Congress, introduced by Senator Owen of Oklahoma, of which little is heard, but which may be said, without exaggeration, to be one of the most important, if not actually the one vital, war measure before that body to-day—more so as regards the outcome of the struggle than either the Chamberlain or the Overman bill. Whether the President must accept more advisers, or whether he is given the power virtually to go it alone, the war will go on, troops will be trained, equipped, sent to France, and will there give the gentle Hun the surprise of his life; but unless the health of these same troops is carefully guarded, and they are protected from endemic and epidemic disease and maintained in hygienic surroundings, both here and abroad, the war will be lost; at least it will not be won with our aid. The men to whom the health of our soldiers is theoretically entrusted are the members of the Medical Corps, both regular and reserve. We say theoretically since practically the medical officer has but little voice in the medical and hygienic care of the army; for whether or not his recommendations or criticisms reach headquarters depends entirely upon the will of one or more line officers who are his superiors in rank. As Dr. Lambert, Dean of the Medical Department of Columbia University, has well said in a recent interview: "All inferior officers must make their reports through the superior officers of the line who command, and the medical officers are no exception. A medical colonel must report through the brigadier general of the line, and be blocked if he attempts anything that benefits his men unless the line officer desires it. And of course the regimental surgeons with the rank of captain, and even major, must report through the colonel in command of the regiment, and he to the brigadier general in command of the brigade, and he to the major general in command of the division, before any report or suggestion for improvement is allowed to go up to headquarters staff and the question be actually taken up with the general in command."

It is to remedy this deplorable and dangerous condition that the Owen bill has been introduced. At present there is but one officer, the surgeon general, in the Medical Corps above the grade of colonel,

but if the Owen bill passes there will be in the Medical Corps, with the present enrollment of about 15,000 officers, 37 major generals, and the same number of brigadier generals, 600 colonels, 1,200 lieutenant colonels, and those of lower rank in proportion. Then the medical man could speak with authority, and could make his voice heard at headquarters, regardless of the opposition of some medically ignorant or unfavorably disposed line officer. The bill would benefit especially the officers of the Reserve Corps, recruited for the war from civil life, for it would make them—at present barred from all grades above major—eligible equally with the officers in the regular army for promotion to higher rank.

The members of the Medical Reserve Corps will also benefit personally if this bill is passed, for they will receive the increased pay which goes with their higher rank—a matter of secondary importance in comparison with the health of our fighting men, yet one of justice to those who have abandoned lucrative practices at the call of patriotism, and one that would enable many more men to give their services who now are deterred by the necessity of providing for their families. A man with a large family who has an income of ten to twenty thousand dollars a year from his practice should not be forced to abandon this and support his family on the \$3,000 a year of a major or the \$2,400 of a captain. The medical profession has responded nobly to the country's call, and when more men are needed more will respond, whether the Owen bill becomes a law or not; but the response will naturally be more prompt and more hearty if the volunteer knows that he will not have to leave his wife and children in want. The physicians of the country have therefore both a patriotic and a personal interest in this measure, and we would urge them to exert what influence they possess with their senators and representatives to secure the passage of the bill, and they should do this without delay.

THE USE OF X-RAYED GUINEA PIGS IN THE DIAGNOSIS OF TUBERCULOSIS.

THE unequivocal diagnosis of tuberculosis is so frequently dependent upon the element of time for the actual demonstration of tubercle bacilli that any method which will assist in arriving at a more rapid conclusion is worthy of consideration. It is a well-known fact that a comparatively high percentage of pathological fluids and excretions derived from individuals afflicted with tuberculosis fail to reveal the presence of tubercle bacilli, even after careful search under the best possible technical conditions. Aspiration fluids generally, and pleural exudates in particular, in addition to sputum, pus, and urine, often contain so few bacilli as to escape detection in the course of routine examinations. Such specimens are usually inoculated into guinea pigs to determine the presence or absence of tuberculous infection. It is generally assumed by path-

ologists that if after the lapse of six weeks the animal shows no gross or microscopical evidence of the disease at autopsy the injected material did not contain tubercle bacilli. Such an assumption is, on the whole, correct, but, like so many biological tests, it is not absolutely infallible, for it has been shown that some guinea pigs have sufficient resistance to overcome a mild infection. The time limit of six weeks is a very important factor in both diagnosis and treatment. Many things may happen during this period to a patient who is infected with this dread disease. On the other hand, a fairly large number of guinea pigs, when inoculated with positive material, succumb to the infection, or exhibit definite evidence of it in a much shorter space of time.

Experimental work during the past two years has brought to light some interesting data in regard to the effect of x-rays on the inoculated animal. If a guinea pig is inoculated with tubercle bacilli, and then subjected to different doses of the x-ray at varying intervals, the lymph nodes will develop lesions sooner than if the animal is left untreated. In the most recent contribution to this subject, W. H. Eckford (*Journal of Laboratory and Clinical Medicine*, Dec. 17, 1917) gives the results obtained by this technique, whereby susceptibility to the experimental infection is increased. Eckford recommends that the substance for inoculation be suitably prepared by washing, and digesting the mucus or fibrin when necessary. The specimen is then centrifuged and a uniform amount of the sediment is injected into both groins, as well as intraperitoneally. The guinea pig is then exposed every second day to a five-minute dose of roentgen rays for at least three exposures. If a nodule appears, and is still present in two weeks, it is removed under local anesthesia, smeared, and examined for bacilli and tuberculous lesions. If positive, the result is reported at once, thus gaining possibly four weeks; if negative, the pig is allowed to live for the usual six weeks and then autopsied. Eckford has found that removal of a nodule in two weeks is usually diagnostic. When negative, visceral or peritoneal evidences of the disease may develop subsequently. Frequently repeated doses of the rays seem to be more effectual than a single application.

The mechanism whereby the disease is accelerated in the guinea pig has not been entirely explained. It is known that destruction of lymphoid cells in the glands causes lowered resistance to the action of tuberculous toxins, but that this is the full explanation is not generally believed. In any event, whatever reason is forthcoming for the phenomenon, the procedure is apparently of sufficient practical value to merit a routine place in diagnosis when the inoculation test is to be utilized.

CAFFEINE AND URIC ACID.

WHILE much of the romance connected with the activities of uric acid in the body seems to be, for the time being, dropping out of medical lore, at least in regard to the influence of uric acid in the

causation of gout and nephritic conditions, yet it must remain as an important indicator of the nature of the food ingested and the form of metabolism following. Uric acid is an end product of purin metabolism, that is, an oxidation product of the purins. The elimination of this substance in the urine is increased with the ingestion of foods rich in purin, and whether it is the ingestion of such food that is the direct cause of certain of the specific medical conditions or whether the action of such foods and their end products is only one of general irritation and the causation of fibrosis and degeneration is much of a question. Suffice it to say that the purin free dietary is considered the simpler dietary and recommended still as a prophylactic measure against degenerative conditions and in the treatment of them when they arise. Proteins and foods rich in nuclein are also rich in purin and increase the amount of uric acid eliminated. Yet the same significance to the purin free dietary is no longer accorded in the treatment of gout or the degenerative conditions as previously, since the question of the influence of uric acid has fallen into doubt.

Investigations made last year by Mendel and Wardell have definitely placed coffee, tea, and to a lesser extent cocoa in the class of substances which if ingested will cause a marked increase in the output of uric acid, that is, an increase in the activity of the purin metabolism. It is hard to say whether the objection to the excessive use of these beverages lies in the stimulation of this metabolism or whether it lies in the fact that the caffeine contained in them is a vegetable poison. The known physiological effects of the ingestion of excessive amounts of coffee has led to the manufacture of a number of decaffeinated products, purposed to obviate the effect of excessive purin metabolism as well as the untoward physiological or poisonous effects. These products have become very popular with the public.

Only a very small portion of the ingested caffeine appears in the urine unchanged; most of it is demethylated and the resultant purin substances are oxidized to uric acid. Yet it has been variously reported by many experimentors that in animals the ingestion of caffeine has no effect to increase the output of uric acid. In dogs these findings can be explained on the ground that the end product of purin metabolism is not uric acid but allantoin. In man the results of experiment seem to point to a decided increase in the uric acid output from caffeine. When a man is placed on a purin free diet of eggs, milk, bread, butter, and fruit until the endogenous level of uric acid is reached and coffee then added, it is found that there is a marked increase in the amount of uric acid eliminated in the urine. With the removal of coffee and the retention of the purin-free diet the endogenous level of uric acid is again soon reached. On the other hand, the addition of one of the preparations of decaffeinated coffee to the purin-free dietary does not raise the uric acid eliminated, but the latter is raised when

caffeine is added to this combination. This would seem to point rather definitely to the caffeine in the coffee as responsible for the increase in the purin metabolism and at the bottom of the increase elimination of uric acid. Similar experiments with tea (*J. A. M. A.*, June 16, 1917) have brought out the same points. The increase in the elimination of uric acid seems to be proportional to the ingestion of caffeine. The increase in the amount of uric acid eliminated after the ingestion of caffeine is said to be equal to the quantity of uric acid which could be obtained by the demethylation and subsequent oxidation of the caffeine ingested in the proportion of about 10 or 15 per cent.

THE DEMENTIA PRECOX PROBLEM IN PRIVATE PRACTICE.

It is quite possible that a great many physicians are ready to deny that there exists, at least to any extent, such a problem as indicated by this title. Looking back upon the busy years of his practice, the general practitioner doubtless recalls now and then the case of a youth in the family of one of his patients who became insane, as the saying is, and was carried off to a State hospital where later on it was given out he had dementia precox. Few, unless they have ridden the psychiatric hobby, have much of an idea how dementia precox originates, its early manifestations, and its prevention, looking upon it as rather a medical curiosity, or as one of those bolts from the well-known blue. That such a condition is as much a disease as malaria or typhoid fever does not figure in their everyday calculations.

The practising physician should be familiar first of all with the "precox personality," the shut-in type of disposition that tends to brood over problems, to withdraw from everyday life, and become absorbed in phantasies and introspection. Of course, this sort of conduct is often regarded as a phase of the humors of adolescence and assumed to be but temporary. But too often it is indicative of the sort of make-up which, when brought face to face with stress, turns in upon itself and retreats behind the fantastic barriers of a psychosis. It is a question yet how much can be done in the way of prophylaxis in this problem. Whether a careful analysis and re-education will equip such a nature to battle successfully with reality or not is doubtful, certainly many cases seem fated so to succumb, but others may perhaps be reclaimed. At least it is worth a trial, and the saving of even a few of our youths from the curse of dementia precox will be well worth the effort.

Too comfortable, anyway, is the attitude toward the humors of adolescence. To be restless and eccentric at this time of life may be merely an evidence of that condition of adolescent irritability described by Wm. Healy, where the prognosis is good under reasonably intelligent parental handling, but on the other hand it may be that such symptoms are the precursors of a far more serious state of affairs,

of a psychosis that means thirty, forty, or fifty years dragged out in an insane asylum. Examination of peculiar children or eccentric adolescents by a qualified psychiatrist is the only way to be sure and such a consultation may be productive of advice which would be sufficient to turn the scales in the right direction and prevent a lifetime of misery.

INTRAVENOUS MEDICATION IN THE XVII CENTURY.

A WRITER in the *Bulletin of the Progrès Médical* for December 22, calls attention to the fact that in the XVIII century the practice of intravenous injections was already old and condemned. His authority for the statement is Heister. The origin of the procedure is involved in some obscurity and the doubtful honor of priority was awarded to several practitioners. The then universal custom of venesection could have suggested it to any medical man. Heister stated that this "chirurgia infusoria," as it has been termed by some sponsor, had enjoyed its greatest vogue in the XVII century, about 1660-1680. The indications seem to have been much the same as they are to-day—rapid medication in desperate conditions in which buccal exhibition was impracticable, notably apoplexy and cyanosis. This was extended to leprosy, gout, epilepsy, tuberculosis, syphilis, scurvy, and malignant fevers. The results as a whole were hardly fortunate. Purmann tested the injections upon himself and pronounced them harmless. Some authors reported stupor, delirium, and death as sequences, doubtless in part because of the desperate character of the diseases treated. The writer is silent about the medicaments used, but the technique is described and illustrated, the cut being taken from Heister's "Institutiones Chirurgicae," Amsterdam, 1750. While a cannula and bulb figure in the illustration, a syringe was also employed.

POLYSEROSITIS.

THIS affection is not often described in English medical literature, although not uncommon in the annals of Continental medicine. Its not infrequent occurrence in Brazil and Argentina has raised the question of the possible role of a trypanosome in the genesis of some of the material. As the etiology of the European disease is a complete riddle, this view may ultimately throw light on the nature of the malady. At the present time, however, so-called Chagas's disease can only be regarded as a simulator of polyserositis, in which the trypanosome by attacking the myocardium favors the mechanical collection of fluid in the great serous cavities along with enlarged liver and other evidences of cardiac stasis. In true polyserositis there is an active inflammation of the serosæ, while the involvement of the heart is evidently secondary to pericarditis. That true polyserositis occurs in Brazil well appears in certain case reports, for example one by Barroso of Bahia in the *Brazil-Medico* for December 1. Syphilis, tuberculosis, and trypanosomiasis could all be excluded. The case was a classical one of total polyserositis involving all four of the serous sacs which come in contact with the diaphragm. Since in severe infections, commonly with fatal ending, these sacs may be involved, and since polyserositis

is sometimes associated with synovitis, etc., it seems fair to conclude with the author that the condition must represent a masked infection or the sequelae of an infection. The treatment is limited to roborants (hypophosphites) and cardiotonics with diuresis and punctures.

PARADOXES OF THE SENSE OF SMELL.

ACCORDING to Voivenel in the *Progrès Médical* for December 29, psychologists like James and Ellis have written slightly of the sense of smell. On the other hand Baudelaire, a layman, regarded odors as most powerful stimulants to ideation and memory and not a few scientists have dilated on the complicated nature of the olfactory apparatus and its embryological identity with the brain. Among well-known men who possessed a characteristic odor of agreeable nature may be mentioned Alexander the Great, Malherbe, Haller, and Cujas. The ability of various savages to recognize disguised women by the smell is on a par with the fascination of the personal odor of many women for their admirers. In fact this latter element plays a certain rôle in sexual selection which would be much more in evidence if artificial perfumery were less in use. It is not unlikely that misogynists are influenced to some extent by feminine odors which at the same time repel and sexually excite them. The author appears to see in some of Tolstoi's writings a sort of defence reaction of this character.

News of the Week.

Measles in New Jersey.—Measles is prevalent to such an extent in the towns of western Essex County, New Jersey, that the schools and Sunday schools have been closed until the epidemic abates. The schools of Roseland have been closed for two weeks.

Palestine Needs Hospital Unit.—According to advices received by the Palestine Restoration Fund Commission, disease, starvation, and expulsions have reduced the Jewish population of Jerusalem to 33,000, or about 40 per cent. since the beginning of the war. The British authorities have cabled that there is urgent need of a hospital unit. The women's Zionist organization in this country is planning to send one.

Meningitis Closes Schools.—The Board of Health of Columbia, S. C., has closed the public schools, churches, and other public gathering places, in an effort to prevent the spread of cerebrospinal meningitis, of which fifteen cases have been reported in the city.

Anthrax Patient Cured.—William Mathews, the New Brighton, S. I., man who was admitted to Bellevue Hospital on January 27 suffering from anthrax, has been discharged cured. Out of nine cases of anthrax that have come to Bellevue Hospital in the past two years this is the second cure.

A Vote of Thanks to Publishers.—At the meeting of the New York Academy of Medicine, held February 7, 1918, to show its high appreciation of gifts to the library by William Wood & Co. and D. Appleton & Co. of New York, and W. B. Sanders Co. of Philadelphia, the Academy passed unanimously a vote of thanks to those publishers.

The Bankers' and Brokers' Auxiliary of the United Hospital Fund of New York announces subscriptions to that fund amounting to \$31,331.

Gifts to Columbia University.—At a recent meeting of the trustees of Columbia University announcement was made of a gift of \$3,000 from an anonymous donor for research work in war problems and a gift of \$5,000 from Clarence MacKay for surgical research work.

The National Committee for Mental Hygiene held its tenth annual meeting in New York City on February 6. Dr. Lewellys F. Barker, the president of the Association, emphasized the importance of the measures taken by the Medical Corps of the Army to weed out men who would collapse under the stress of battle in increasing the efficiency of the American fighting forces in Europe. Dr. Frankwood E. Williams made the statement that the army cantonments have better facilities for the care and treatment of soldiers suffering from nervous and mental diseases than any city of 40,000 people in the United States. He said that up to the present about 300 psychiatrists and neurologists had been commissioned as officers of the Medical Reserve Corps, and were now doing duty in the various camps. The National Committee for Mental Hygiene elected the following officers: *President*, Dr. Lewellys F. Barker of Baltimore; *Vice-Presidents*, Dr. Charles W. Elliot, Dr. Walter B. James of New York, and Dr. William H. Welch of Baltimore; *Treasurer*, Mr. Bannard; *Medical Director*, Dr. Thomas W. Salmon; *Associate Medical Director*, Dr. Frankwood E. Williams.

Appointments at Columbia University.—Dr. Russell A. Hibbs of the University of Louisville has been appointed Professor of Orthopedic Surgery in the College of Physicians and Surgeons of Columbia University.

Dr. Eugene W. Caldwell of Bellevue Hospital Medical College has been appointed to the newly established Chair of Roentgenology.

Dr. Vera Danschakoff, formerly of Moscow, has been appointed assistant professor of anatomy.

Dr. I. H. Goldberger has been appointed Special Lecturer of Child Hygiene in the School for Oral Hygiene, Columbia University.

Appropriation Asked for New York Quarantine Station.—Secretary of the Treasury McAdoo has asked Congress for an appropriation of over \$1,500,000 for the purchase and operation of the New York Quarantine Station. He has requested an appropriation of \$1,395,275 for the purchase of the property from the State of New York and \$275,000 with which to operate it during 1919. In making the request for this appropriation Secretary McAdoo cites reasons why the station should be taken over by the Federal Government.

Pneumonia Deaths Continue to Increase in New York.—According to the records of the Health Department of New York there were reported for the week ending February 9, 1,772 deaths for the Greater City, of which 355 were due to pneumonia, as against 1,736 for the preceding week, of which 325 were due to pneumonia.

Brooklyn Hospital Appeals for Funds.—According to a statement recently issued by the president of the Jewish Hospital, Brooklyn, the expenses of that institution for the past year have exceeded

those of previous years by \$53,000. Thus far the expenses of the institution have been met by the directorate, but the burden has now become so heavy that it has become necessary to make an outside appeal. The Jewish Hospital last year treated 6,289 patients, an increase of 840 over the previous year.

Reorganization of State Board of Charities.—There is a bill before the New York Legislature providing for a reorganization of the State Board of Charities. Instead of an unpaid board of twelve members appointed by the governor from the districts of the State the bill provides for a board of nine members, of which at least one must be a woman and three of whom are to be paid. Under the proposed plan the members are to be appointed by the governor from the State at large and are to possess special qualifications specified by law. The three paid members are the president and the chairmen of the two new bureaus within the board, the Bureau of Mental Deficiency and the Bureau of Dependent Children. Those requiring special qualifications are an educational specialist, a specialist in tuberculosis and one in psychiatry, a general practitioner and a lawyer.

Plan for Fighting Tuberculosis in New York State.—The *Bulletin* of the New York State Department of Health for January shows that progress is being made in complying with the laws of 1917 which made mandatory the erection of a tuberculosis hospital in every county having a population of over 35,000. This law has affected twenty counties in all, of which the department has inspected sites, with the exception of Sullivan and Washington, which counties have appointed site committees. Sites have been approved in eleven counties and are being prepared for consideration in six others. The Tuberculosis Committee appointed by the Health Commissioner in July, 1917, has adopted a state-wide program for the following year, the main features of which are: The establishment of adequate tuberculosis hospital provision for each county in the State on the approximate basis of one bed for each average annual death in such county; the inspection of local tuberculosis hospitals during the year 1918, and the promotion of the adoption by them of the recommendations made subsequent to this department's survey in 1914-1915; the formulation of plans for the development of the county tuberculosis hospitals as the campaign center in each county; cooperation with the superintendent of Ray Brook in the establishment of a course of instruction for hospital superintendents; systematic efforts to secure the attendance of all local tuberculosis hospital superintendents at the Ray Brook courses of instruction; promotion of a systematic plan for the protection of children from tuberculosis infection, and, as an alternative to dispensaries, the establishment of out-patients' service and physicians' clinics to be conducted by the county hospital superintendents in cooperation with health officers. The program also includes a widened range of activities for nurses and health officers in anti-tuberculosis work.

Medical Society Elections.—THE PARK REGION DISTRICT AND COUNTY MEDICAL SOCIETY held its annual meeting at Fergus Falls, Minn., on January 13, at which time the following officers were

elected: *President*, Dr. A. Kessler of Battle Lake; *First Vice-President*, Dr. P. Boyeson of Pelican Rapids; *Second Vice-President*, Dr. W. L. Patterson; *Treasurer*, Dr. C. O. Estram of Fergus Falls.

THE MCCrackEN COUNTY MEDICAL SOCIETY, at its annual meeting in Paducah, Ky., on January 11, elected the following officers: *President*, Dr. H. P. Linn of Paducah; *Vice-President*, Dr. V. L. Powell; *Secretary-Treasurer*, Dr. H. P. Sights; *Censor*, Dr. J. Q. Taylor.

THE CASE COUNTY MEDICAL SOCIETY, at its annual meeting in Fargo, N. D., recently, elected the following officers: *President*, Dr. John Rindlaub; *Secretary-Treasurer*, Dr. C. N. Callander.

Obituary Notes.—Dr. GEORGE W. WESSELLIUS, a graduate of the Detroit Medical College, in 1886, died suddenly at his home in Grand Rapids, Mich., on January 7, aged 69 years.

Dr. JOHN W. RAWLS, First Lieutenant in the United States Medical Reserve Corps, a graduate of Tulane University, in 1900, died recently of tuberculosis at his home in Dallas, Texas, aged 40 years.

Dr. MARION G. CHANCEY of Tampa, Fla., a graduate of the Medical University of the South, Sewanee, Tenn., in 1903, died of tuberculosis at the home of relatives, in Pierra County, Georgia, on January 11, aged 40 years.

Dr. MAXWELL GOLDMAN, a graduate of the Boston University School of Medicine, in 1913, died at his home in Boston, after a long illness, on January 14.

Dr. ROYAL HATCH, a graduate of Harvard Medical School in 1904, and chairman of the Wellesley Board of Health, died after a brief illness at his home in Wellesley, Mass., on December 29, aged 39 years.

Dr. WILLIAM E. IRWIN, a graduate of Vanderbilt University Medical Department, Louisville, Ky., in 1878, died suddenly of heart disease at his home in Owensboro, Ky., on December 28, aged 62 years.

Dr. CHARLES H. PRINDLE of Chicopee, Mass., a graduate of the University of Vermont Medical College, in 1885, died of pneumonia on January 21, aged 62 years.

Dr. ALBERT H. VARNEY of Exeter, N. H., died at his home in that city on January 16, at the age of 81 years. He was graduated from the Harvard Medical School in 1857. He was for three years assistant surgeon in the Second New Hampshire Regiment, and was elected to the State Legislature in 1871.

Dr. FRANK WEBSTER THOMAS, a graduate of the Eclectic Medical College, Cincinnati, in 1880, died at his home in Claremont, Cal., on January 11, aged 65 years.

Dr. FREDERICK POWERS of Westport, Conn., a graduate of the College of Physicians and Surgeons, New York, in 1870, died suddenly on January 11, at the age of 75 years.

Dr. HUBERT ANTON SUMPMANN, a graduate of the Chicago Homeopathic Medical College, in 1890, died, after a long illness, at his home in Dubuque, Iowa, on January 9, aged 54 years.

Dr. EDWARD DYER ELLIS of Poultney, Vt., a graduate of Harvard Medical School, in 1877, died at his home on January 26, aged 66 years.

Dr. WILLIAM NELSON HAMMOND died at Philadelphia on January 22, at the age of 44 years. He was graduated from the Atlantic Medical College of Baltimore in 1896, and he was associate professor

of surgery in Hahnemann Medical College and Hospital. He was a Fellow of the American Academy of Surgery.

Dr. MONTROSE GRAHAM TULL died at Philadelphia on January 25, at the age of 55 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1885.

Dr. JAMES WILSON WALK died at Philadelphia on January 19, at the age of 64 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1878. He was in 1892 director of the Philadelphia Board of Charities and Correction, and in 1897 director of the Bureau of Health.

Dr. PETER ANDERSON of New York, a graduate of the Toronto School of Medicine in 1903, died of tuberculosis at the Kingston Avenue Hospital, Brooklyn, on January 30, aged 39 years.

Dr. JOHN A. GORDON, the oldest physician of Quincy, Mass., died after a long illness, on January 25, aged 75 years. He was graduated from Harvard Medical School, in 1869, and was one of the founders of the Quincy City Hospital. He was at one time town physician and chairman of the Board of Health of Quincy.

Correspondence.

SANATORIA FOR DRUG ADDICTS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Some of the newspapers containing reports of my testimony before the Whitney (Senate) Drug Addiction Committee published distorted and absolutely incorrect accounts. I did not contradict them because of my repugnance to newspaper publicity and because I knew that my colleagues would not credit me with such views. Finding however that lies travel much farther than the truth, as I discovered in repeated reiteration of the false report in newspapers outside of the city. I have written the following letter to Senator Whitney, which explains my views:

"My Dear Senator—I want to ask you to help me set myself straight in the following. From the inclosed clipping you will see that I am reported as approving private addict sanatoria as philanthropic institutions. The fact is quite the contrary. I believe they are conducted as all other business enterprises, for profit. . . . My testimony on this point was to meet the absurd and untrue statement of the addict doctor who preceded me that doctors know nothing about drug addiction and that medical ethics are a manifestation of narrowness. I testified that medical ethics were only a code of politeness and that they were more for the protection of the patient than the doctor.

"Nor did I say that my method was the best. The fact is that I have no method, and told your committee that I had no personal experience to offer for comparative results. I only mentioned the water treatment of other diseases to illustrate that, being regarded as an enthusiast on this treatment, my judgment may be warped, and this may be true of those who had specific addict treatment.

"You would do me a great favor to send me a transcript of my testimony as taken down by your official reporter," etc.

I wrote Senator Whitney that Dr. Dana's article in the last number of the MEDICAL RECORD is in every respect exactly like my own testimony given a month previously, and suggested that he obtain it. He wrote me that he would do so.

SIMON BARUCH, M.D.

2. Vaginal Discharge in Children; Study of 255 Selected Cases, with Special Reference to the Question of the Diagnostic and Specific Value of Smear Examinations.—I. C. Rubin has found that of all the cases seen, from the clinical side, the very smallest number were truly gonorrheal, resembling the disease as met with in the adult. A definite history of contact infection, as by pervers (the infectionist theory of Pollock) or through attempts of rape, was obtained in only one case. In two others there was definitely the evidence of a ruptured hymen without such a history of assault. In the vast majority of cases the complications and sequelae of gonorrhea were entirely lacking. The absence of gonorrheal ophthalmia, of urethritis, of joint symptoms and of peritoneal symptoms, in spite of the apparent chronicity of the discharge, certainly makes one reflect that this condition in children is at least different from the gonorrhea of adults. It certainly does not have the virulence nor the tendency to cause metastatic foci as it does in the adult. In this connection Louise Pearce's work on the comparison of adult and infant types of gonococci is both suggestive and significant. She found in working with strains of gonococci from adults and strains from children that, both in agglutination and complement-fixation experiments, these strains differed so uniformly that they could be distinguished as two distinct types corresponding to the clinical source of the strains. Her experimental material was derived from 6 cases of vaginitis in children, 3 cases of gonorrheal ophthalmia (a) neonatorum; (b) girl 18 years with vaginitis; and (c) boy 15 years with urethritis; and finally 8 cases of gonorrhea in adults. It is of the greatest significance to note that the strains of gonococci isolated from the three cases of ophthalmia are classed by Pearce with the adult type. In the cases which had come under Rubin's observation there was not a single instance of ophthalmia. Rubin considers that if the disease were really as prevalent as we have been led to suppose, we ought to see more dangerous sequelae later on in life. We ought to see more pyosalpinx and pelvic peritonitis in young girls. We know, however, that practically in every instance where such condition obtains in a young girl of 14 years and upward there is always a definite history of recent exposure, with all other signs and symptoms of a gonorrheal infection. That a true gonorrheal infection does occur in children cannot be denied; there have been enough reports where the gonococcus of Neisser was recovered from metastatic foci in the body joints, eyes, etc., associating a gonorrheal vaginitis. The actual incidence of the latter in children is probably very small. Rubin's clinical experience coincides with that of V. Pirquet and V. Reuss, for example, who stated that they see in their very large clinical material only 5 or 6 cases yearly. If the majority of children having vaginal discharge are infected with the gonococcus, it must in all probability be a different microorganism from that described by Neisser as occurring in adults. Whether it is some other organism, however, can be established only by proper bacteriological and serological tests. Thus the well-recognized infectious vaginal catarrh which spreads through hospital

wards may have some other bacteriological etiology than the gonococcus. Some other method of diagnostic control than that offered by smear examination must be available if we are to treat it intelligently and scientifically. He has found not only the greatest discrepancy between the clinical picture and the smear report, but in a series where two different bacteriologists made the examination there was the greatest contradiction in their reports on the same material examined. The bacteriologists were of unquestioned reputation, with the best facilities for bacteriological examination. While this difference of opinion is possible in any other laboratory test, in this work it adds considerably to the other difficulties in coping with the vaginitis problem. From his experience with these cases he is led to the following conclusion: To establish the diagnosis of *gonorrheal vaginitis* in children and infants, it is necessary to have: (1) A purulent discharge from the vagina. (2) The intracellular Gram-negative diplococcus of Neisser must be discovered in the pus cells (smears and cultures are facilitated by the endoscope). (3) This organism must further be grown on suitable culture media and properly identified as the gonococcus. (4) In case of doubt, complement-fixation tests and agglutination tests should also be resorted to. In the absence of these tests we are not justified in considering any vaginal discharge in children as gonorrheal, nor are we justified in treating it as such. *The smear examination, even by the Gram stain of secretion or discharge from the vagina, is unreliable and misleading, and hence valueless as a method of diagnosis.* The desideratum in the problem of vaginitis among children, therefore, is more complete and scientific bacteriological study, including animal inoculation.

2. The Psychological, Physiological, and Pharmacological Basis of Nicotinism, Alcoholism and Morphinism.—James L. Tracy points out that mankind does not come up out of the past without struggles. Not all of heredity is progressive, nor is it altogether retrogressive. There is more progression, but of course some backward pull of an ignoble past. Progressive inheritance translates the stresses of life into terms of inspiration for harder work, while retrogressive instincts demand relief from the normal stimuli to better and more persistent work. This demand is the pull of barbaric contentment. This inheritance weakness fails to see that the stresses of life, when rightly made use of, are the only agencies that are beneficently and with unchanging aim bringing humanity from lower to higher levels of civilization's attainments. This instinct prompts mankind to seek freedom from care in some narcosis. The hereditary weakness, the ancestral degeneracy yearning for a sense of freedom from care, is everywhere more male than female. It is the instinctive looking back of a courageless mentality to the scenes and place and time of some lower plane of living. Out of this weakness grow all forms of superstitious beliefs and practices. The loss to humanity from the cutting out through narcosis of the inspiration from full appreciation of the meaning of life's realities is incalculably great. It is impossible to think of courage or of cowardice without thinking about the nerve cell—the degenerative nerve cell. The riddle of psychophysiology is to tell which came over in heredity, the cowardly thought or the verveless nerve cell. Not all of the powers of the inherited nerve cell are cowardly, but no really courageous nerve cell ever asked for narcosis. Tracy deals with the hereditarily craved and invited narcosis, and not with the man behind the narcosis. He deals with the impulses of a sickly nerve cell combining with a feeble will power to form a mind. It is a mind and neuron staying in the evolutionary game, but which choose while fighting to be rendered oblivious

to surroundings. They prefer to work as in a treadmill. They are still conscious of the persistence of life's facts. They know that as soon as the narcosis passes off, the facts will reappear to again trouble them. This accounts for the bitter fight that the beguiled will and the soothed nerve cell put up against interference with their comfort. No study in the realm of scientific medicine is of more practical importance than is the study of the hereditary degeneracy that underlies the universal dread of meeting the so-called ills to which flesh is heir. This dread of reality in some people tries to hide behind the ecstatic state of mind that denies the existence of disease. Of the three principal narcotics used in this country, nicotine for several reasons leads in popularity. It most quickly satisfies the longings of the storm-tossed mental and inept neuron. Nicotine exalts the ego. The medical matter involved is that the end results of nicotine narcosis are never as good as the nonnarcotized man would have been capable of. Alcohol is the second on the list of the three narcotics. Alcohol may almost be said to be the first thought of degeneracy weakness. It has the psychical handicap that its narcosis carries with it some degree of shame for having used alcohol. The ego feels humiliated. Alcohol supplies a felt want in all classes of people. The narcosis is of the same neuron in all grades of mentality, but necessarily the intoxication is at different intellectual levels. The one common desire in all users of alcohol is to be made oblivious to the distressing things of life. The apotheotic aspect of alcoholic intoxication makes for unpopularity. Morphine narcosis is one of the most cowardly of intoxications. Morphine caters to the death part of the nerve cell. Public opinion prefers life to death and condemns morphinism because it slinks and cowers. Tracy submits the following propositions: The general open public use of some form of narcotic is a matter that demands serious medical consideration. The use of narcotics has its origin in the retrogressive cowardly instincts that are ever coming up with man out of the past. The other basis for the public use of any narcotic is in the voice of public opinion. The public use of narcotics represents the intelligence and moral level of public opinion, but the commendation or condemnation of a narcotic by public opinion does not in the least affect the workings of physiological laws.

5. Syphilis as a Cause of Stillbirths: Analysis of Forty-eight Stillbirths Occurring in Fifteen Hundred Obstetric Cases at the University of Michigan Maternity Hospital.—R. A. Bartholomew first defines the term stillbirth as the birth of a child which has reached the stage of viability, at the twenty-seventh or twenty-eighth week, but in which cardiac action ceased during or before birth. The number of stillbirths in this series is 32 per thousand, which falls within the limits found for New York City, where the number varies from 30.3 to 59.2 per thousand. Out of 1,867 stillbirths reported in Manhattan in a period of seven months, 1,331, or 71 per cent., occurred during the period from the seventh month on. Theoretically, these children would

have had a chance to be born alive, had the mother received proper prenatal and natal care. The great majority of the patients admitted to the maternity hospital are illegitimately pregnant, and hence come to the hospital at about the seventh month, as a rule, when it becomes difficult to conceal their condition any longer. Each case receives an examination and a Wassermann test, and if syphilis is indicated a more careful examination is made and treatment instituted. Out of the forty-eight cases of stillbirth, twenty-one infants were born in a macerated condition. In sixteen of these twenty-one cases, a necropsy was performed and showed congenital syphilis in nine cases, or 56.25 per cent. Of the other seven negative cases, two were so badly decomposed that no diagnosis could be made, but it is strongly probable that one or both were syphilitic. It has long been recognized that from 60 to 80 per cent. of stillborn macerated babies are syphilitic. Hence, the good effects of all measures tending to reduce the frequency of syphilis, which has been estimated at at least 10 per cent. of the population, will be seen at once in a reduction of stillbirths. Syphilis complicating pregnancy will be diagnosed more frequently if the Wassermann test is made more universally available. The problem of greatest interest and importance is that of prevention. He has discussed the factor of syphilis in some detail because of the fact that this disease alone accounts for fully one-third of the cases of stillbirth and is by far the largest single factor. Bartholomew concludes from his thorough study that there is need for the adoption of a uniform definition of stillbirth and of compulsory reporting of stillbirths, in order that statistics on this important cause of infant mortality may be improved. Syphilis is the causative factor in at least one-third of the stillbirths from the time of viability to full term, and a Wassermann reaction is strongly indicated in cases in which there have been suggestive clinical symptoms, unexplained abortions, or premature labors with macerated babies. A combination of mercury and salvarsan is more effective in assuring the birth of a healthy infant than salvarsan alone. Important confirmative evidence in the diagnosis of syphilis can be obtained from microscopic examination of the placenta, or in case of stillbirth, from examination of the fetal liver by the Levaditi method. More efficient and practical training in obstetrics, and safer surroundings for the patient during confinement will prevent some of the stillbirths resulting from other complications of pregnancy and obstetric emergencies. But there will always remain a considerable number of stillbirths from unavoidable causes.

2. Heart Failure and Pregnancy.—James Mackenzie points out that heart failure is essentially a question of myocardial efficiency. He describes the force possessed by the heart as of two kinds, a force which maintains the circulation when the body is at rest—the rest force; and a force called into play when effort is made—the reserve force. Heart failure begins by the diminution of the reserve force, and is made manifest by a limitation of the power of the heart to respond to effort. All failing hearts show a limitation of the field of cardiac response—the first sign being the patient's consciousness that certain efforts which he used to make with ease now give rise to distress. But healthy hearts may show these signs when there is the added burden of pregnancy, for the condition then resembles an individual undertaking an effort with an impaired heart. Many healthy hearts burdened by pregnancy show distinct signs of inefficiency, and yet there is no danger. The notion that the left ventricle hypertro-

phies to meet the burden of pregnancy is not based upon trustworthy evidence. What does happen in every healthy woman is a limitation of the heart's power to respond to effort—a diminution of the reserve force, greater in some cases than in others. A careful investigation which Mackenzie carried out in 100 women before pregnancy, during pregnancy, during confinement and the puerperium, showed no evidence of that hypertrophy which is supposed to meet the increased demands, for the increased demands were only met by calling upon the reserve force. As the growth of the abdominal tumor proceeded the diaphragm was pushed up, the sides of the chest widened, and the heart was displaced upward and to the left, so that the apex beat was frequently felt in the fourth interspace outside the nipple line. With the emptying of the uterus the heart's position shifted to the normal position. While the exhaustion of the reserve force gives rise to the same symptoms whether it is a healthy heart overburdened or a heart failing from disease, it is the extent to which the signs of cardiac inefficiency go and the progress of the failure which serve as a guide. The most striking phenomena of the progress of heart failure are the onset of dropsy, breathlessness gradually increasing till the patient has to sit up, edema of the lungs, and persistent increase of rate or violent beating of the heart on exertion. In regard to dropsy there is this to be remembered, that it frequently occurs in pregnancy from other causes than heart failure—in kidney affections and from pressure of the uterus upon the abdominal veins. When it is present it must not of itself be taken as an indication of a failing heart, but only when there are present the other symptoms of heart failure. It is unnecessary to insist upon orthopnea. When this stage is reached in heart failure the sooner premature labor is induced the better. Edema of the lungs is probably the most reliable guide. When carrying out his investigations it was his custom to begin the examination of the patient by finding out on which side she lay, and then get her to sit up, and auscultate the base of the lung on that side. In many healthy women he found during the later stages of pregnancy that the first deep inspiration was accompanied by numerous crepitations, and that the inspiration dispelled them, so that they were not heard after. In cases that did badly these crepitations did not disappear, but tended to persist, so that their continual presence, coupled with an impaired percussion note, is such a grave sign as to indicate the need for terminating the pregnancy. Termination of the pregnancy is indicated in mitral stenosis when edema of the lungs persists in spite of sitting up in bed or when the heart-rate is persistently over 100 with violent palpitation on the slightest effort. The dangers in aortic regurgitation are so great and yet so difficult to anticipate that he would recommend the termination of pregnancy in all cases when the woman has a "Corrigan" pulse, and when there is a distinct forcible apex-beat outside the nipple line.

3. Antenatal Syphilis: Suggested Action of the Chorionic Ferments.—Amand J. Routh points out that under the action of salvarsan, etc., as well as spontaneously, the mature spirochetal spiral becomes broken up transversely into granules, and that in a suitable environment these granules are capable of development into the mature organism after a short or long period of biological activity. Infection by the granules in congenital syphilis can apparently occur during pregnancy, and if the granules are kept quiescent it is prob-

able that the infected individual (mother or child) would give a negative Wassermann reaction after the birth so long as mature spirochetes were absent. If congenital syphilis is to be checked before the embryo is destroyed it must be dealt with locally at its source, and from the very first days after fertilization and infection. It seems obvious that the embryonic tissues could not during the first hours or days produce antibodies which could destroy spirochetes. Routh suggests that the trophoblastic chorionic ferments produced by the syncytial cells of the fetal chorionic villi are not only able to break up the infective spirochetes into granules, but can, by their continued action, keep the granules quiescent and powerless to develop into the mature organism till after pregnancy, when the ferments soon cease to be present. The biological activity of the granules, unless restrained by other substances, would then be resumed, and mature spirochetes would be developed. He proposed explanations of the four following problems, founded on the spirillolytic action of the chorionic ferments: (1) Why may a pregnant woman who in due course either has a stillborn or a living syphilitic child have a negative Wassermann reaction during pregnancy and for some time afterward? (2) Why are some syphilitic children negative at birth and for some weeks afterward? (3) Why are spirochetes so rarely found in abortions, even though alternating between stillbirths, in the tissues of which they are swarming? (4) How do these suggestions of the spirillolytic action of the chorionic ferments help to explain the truth of the original words of "Colles's law"? His conclusions were as follows: (1) The "granules" are the result of the "spirillolysis," or breaking up of the *Spirocheta pallida*. (2) The "granules" are infecting agents, being in fact spirochetes in the granule stage. They are able to develop into the mature spirochete in a suitable environment, or may become biologically inactive and remain latent for short or long periods. (3) Chorionic (syncytial) ferments are present at the point of interdigitation of the fetal and maternal portions of the placenta. Their action is primarily trophoblastic to enable the delicate chorionic villi to penetrate the uterine mucosa and to open up maternal blood vessels, so that the ovum may find for itself a resting place with nutritive blood spaces round it. As a result of the destructive action of the ferments upon the maternal tissues, so-called syncytiotoxins are formed, but appear to be at once neutralized by so-called syncytiolysins. If not thus neutralized, maternal and fetal toxemia may occur. (4) The chorionic ferments (or their derivatives) are suggested as being capable of exercising their destructive properties upon the *Spirocheta pallida*, which may either be in the maternal intervillous, or fetal intravillous tissues, both of which are in intimate relations with the syncytial cells of the villi whence the ferments arise. (5) This destructive action of the chorionic ferments upon the spirochete breaks it up into granules. (6) He further suggests that during pregnancy it is the continued action of the chorionic ferments upon the granules which may render them latent and biologically inactive, and perhaps in a few cases may destroy them. (7) After the pregnancy, when the chorionic ferments cease to be present in the tissues of the mother and child, the granules, wherever they may be, may develop into mature spirochetes. (8) The success or failure of the chorionic ferments to protect the mother and child from spirochetal infection would depend upon (a) the virulence of the infection, which tends to diminish, owing to the presence of more maternal antibodies, with each successive pregnancy; and (b) upon the source of the infection. Infection is probably most difficult to arrest in a "mixed transmission," or in a true maternal infection, where attempts at infection of the embryo would be constantly proceeding throughout the pregnancy. It is probably least severe, and most easily countered by the ferments, when the primary infection is paternal, for it may then be a single infection only, and probably not capable of repetition if the primary infection be arrested. 9. The Wassermann reaction in mother and child appears to be negative if infection has been only by spirochetes in the granule stage, so long as the granules remain biologically inactive and the mature organisms are absent.

Berliner klinische Wochenschrift.

November 19, 1917.

The Technique of the Open Treatment of Wounds.—H. Marx describes his procedure for continued moistening of wounds. The wounds are simply covered by a gauze dressing and a band of flannel, deprived of all trace of grease, is folded in several layers over the gauze and dips into a jar containing the liquid, hung above the bed. The solution employed by Marx is a hypertonic solution of NaCl, which he prefers to Dakin's formula. The advantages of the treatment are the comfort derived by the patient, the absence of scab formation over the wound surface, and stimulation of the secretions without causing any tissue change or destruction. Any fear of hemorrhage occurring contraindicates the use of this procedure.

War Experiences with Malaria.—F. Munk describes how malarial patients are treated in barracks with automatically closing doors. There is an antechamber of from 2 to 3 meters broad, so that both doors are never open at the same time. The antechamber is freed from all mosquitoes every day when any are to be found. Since adopting these measures (the windows are also screened with wire nets) the writer has never observed a case of the disease contracted in the hospital. Besides these measures, the patients are not allowed to go out in the evening, and no patient is discharged until all parasites have disappeared from the blood. The writer is of the opinion that the concentration of malarial patients in special hospitals is more effective in results than when they are allowed to mingle promiscuously with other patients. The tertian type is the most common form encountered. As to foci of contagion, swampy land leads the van. Next in frequency are agglomerations of men, undoubtedly because there are many germ carriers among them. The majority of cases observed by Marx offered their maximum of frequency during the months of May and September.

Münchener medizinische Wochenschrift.

November 20, 1917.

Recurring Puerperal Anemia, Followed by Osteomalacia, Considered as Endocrine Disturbances.—Naegli considers chlorosis as an affection pertaining to the domain of the endocrine system. Its exclusive development in the female and its eclosion at the time of puberty are certainly reasons of considerable weight in respect to this theory. In order to uphold this line of reasoning, Naegli reports the case of a woman who, at each pregnancy, presented an anemia gravis, quite independent from any considerable loss of blood, and at the same time presenting the phenomena of osteomalacia. Naegli places the seat of the disease in the bone marrow, the determining factor being an excessive functioning of the sexual glands. Besides the hematological and pathological arguments put forward the writer also invokes the favorable action of castration, the exhibition of adrenalin and products of the hypophysis. In the case reported Naegli looks upon the process as an exhaustion of the bone marrow following upon a period of hyperplasia.

The Ultimate Results of Wounds of the Nerves, Particularly from the Standpoint of Operative Interference.—A. Stoffel has had the opportunity of studying various treatments of nerve injuries. His total of 158 cases is shown in the following table: (1) Various injuries, 12 cases; (2) Psychogenous paralyses, 41 cases; (3) Injuries, not operated on and no regeneration, 28 cases; (4) Injuries not operated on followed by spontaneous regeneration, 16 cases; (5) Injuries operated on unsuccessfully, 28 cases; (6) Injuries operated on successfully, 33 cases. In the fortunate cases the successful result was always slow in making its appearance (5 months to 2 years), a fact which probably explains the skepticism of some surgeons as to ultimate results, because they were unable to follow their cases for a sufficiently long time after the interference. The nerve trunks most prone to undergo regeneration are given in the following order: Radial nerve, 28 operations, 19 successes; median nerve, 9 operations, 5 successes; ulnar nerve, 8 operations, 3 successes; peroneal nerve, 8 operations, 1 success; sciatic nerve, 7

operations, 4 successes; musculocutaneous, 1 operation, 1 success. The total results is therefore 33 successful results out of 61 operations, consequently 54 per cent., and of these suture gave 57.1 per cent., and neurolyses 69.2 per cent., while the operative results from plastic operations were nil.

Deutsche medizinische Wochenschrift.

November 22, 1917.

Death from Salvarsan.—M. Dissauer, although appreciating the fact that it is always difficult to prove that death is the result of salvarsan treatment, a fact which has undoubtedly greatly prevented the published data, records a case in which this mechanism must be admitted. In a patient undergoing a mixed treatment with Hg. and salvarsan, the second injection of the latter drug gave rise, after the lapse of forty-eight hours, to general nervous phenomena ending in death in twenty-four hours. At autopsy several hemorrhagic foci were found in the brain, one the size of a plum being situated in the central nuclei. Such accidents are due to a susceptibility peculiar to the patient, and should not be the means of causing rejection of salvarsan treatment, any more so than instances of individual intolerance for other medications noted in certain other morbid processes.

Muscular Plastic Operations in Amputation Stumps from the Viewpoint of Prothesis.—I. F. S. Esser, quite in opposition to Sauerbrück, does not believe that it is ever indicated to shorten the bone in unsatisfactory stumps. On the contrary, the bone ends, covered by the skin, should extend below the muscles in order to allow fixation of the prothesis, thus leaving the joints situated above, their full play. The muscles should be separated into more numerous bundles than is ordinarily done, so as to tunnel each part of the stump in order to form a more evenly distributed padding over the point of application of the prothesis. The tunneling may be accomplished by making Thiersch's flaps, or yet by forming longitudinal muscular flaps which remain connected with the skin flaps of the stump, and this is Esser's method. A detailed description of the technique is given, after which Esser makes a long plea for conservative surgery in wounds of warfare.

Wiener medizinische Wochenschrift.

November 24, 1917.

The Pathology of Edema Disease.—A Schiff gives some details on a disease which he claims to have been the first to describe in May, 1917 (see *Wiener medizinische Wochenschrift*, No. 22, 1917). It is a symptomatic triad consisting of edema, polyuria, and bradycardia. The edema is not related to any renal lesion, because it undergoes its evolution parallel with the diuresis, therefore both these symptoms are the effect of the same cause. A study of the disease shows its great ubiquity. It was, for that matter, mentioned during the Napoleonic wars. It is especially frequent in industrial centers, rare in the agricultural districts of Austria. The writer concludes that everything points to the supposition that edema disease is the result of denutrition. It is a cell change producing an insufficient assimilation of the alimentary chlorides. The hydremia and edema are the consequence of this interstitial chloration. The polyuria, which is nocturnal, and the great quantities of chlorides eliminated (40 to 45 grams in 24 hours) are to be explained by the same reasoning. The direct cause of the affection is rather more due to a qualitative insufficiency of alimentation than to a quantitative insufficiency. A change of diet is often alone enough to control the morbid manifestations. Finally, Schiff incriminates especially the richness in water and the high percentage of NaCl in the food, combined with the alkalinity of an excessive vegetable diet. The treatment is naturally indicated from the etiology of the affection.

The Treatment of Tuberculosis.—L. Wick demonstrates the inferiority in which Austria is placed from the standpoint of treatment of tuberculous soldiers. After offering some general considerations, the writer expresses his desire to see serotherapy more extensively employed, and above all to study it from a scientific standpoint.

La Presse Médicale.

December 20, 1917.

The Teratogenic Rôle of Factors Which Make for Abortion.—Mme. Nageotte-Wilbouchewitch contributes a valuable paper on this subject. Conditions, voluntary or involuntary, which make for abortion have been strangely neglected in the causation of monstrous births and developmental defects. Nothing is so perplexing in teratology as the chronological element. Malformations are naturally associated to a notable extent with the evolution of the embryo and fetus, and the writer considers only such as date from the embryonal period. The distinction between typical and atypical malformations is all important; and the subject can be understood only through studies of the individual cases, of which the authoress cites five. From this number we cite Case II. The parents were young, large and handsome. The offspring were two boys and a girl. The two boys "bred true" in all respects and were an honor to their parents. The girl was large and handsome, but was from early childhood an epileptic idiot. An hereditary taint could be forthwith excluded. No element could be found to explain this anomaly, save one—the mother had made persistent use of "medical" resources to provoke abortion, and the child was born in spite of these attempts. Convinced of the ill consequences, the mother allowed a fourth gestation to go on undisturbed, with the result that the fourth infant was normal. In Case IV there was congenital absence of the radius. The parents were admirably built. It was claimed that the mother, unaware of her pregnancy, had for some unknown reason received abdominal massage. The infant, a daughter, was born at term and was very vigorous. Nevertheless there was absence of the right radius, curvature of the ulna, and other anomalies of the right forearm. On the left the defective development of the forearm was much less marked. Several years later a second infant, perfectly intact, was born. Case V presented complete epispadias and luxation of the fibula. The mother, who had recently conceived without knowledge of the fact, had tried to make a railway train, with the result that she fell in a faint, breathless. This was the second child of very vigorous parents, the first child having bred true.

Correspondenz Blatt für Schweizer Aerzte.

December 15, 1917.

Maternity Tetany.—Guggisberg refers to the earliest description of tetany by Steinman in 1830. In the '80's the thyroid theory came into prominence, but was later demolished by Vassale. At present the parathyroid theory is the occasion of much debate and research. The chief argument against it is the multifold nature of tetany, no less than 8 categories of incidence having been isolated. Under maternity tetany the author includes the gestational, parturient, and nursing expressions. Only women of otherwise normal condition are included. The disease may appear during labor as well as in the puerperium and lactation period. It is often overlooked by the medical man or confused with hysteria. A geographical factor is often in evidence. Multiparæ are chiefly attacked and in the latter half of gestation. It is apt to recur in successive pregnancies and to be aggravated progressively. Labor exerts no influence on gestational tetany. The puerperal and lactation periods tend to exert an unfavorable influence. Clinically maternity tetany differs in no wise from other forms, but individual patients exhibit much variation in intensity and duration. From imperceptible to fatal attacks there are all degrees of expression. There may be a single seizure or a long series with intermissions. Aside from seizures proper there are internal symptoms which may also appear as prodromes or sequelæ. For example, there is a heightened tonus of certain muscles which interferes with finer movements. In chronic cases trophic disturbances may be in evidence in the skin, hair and nails. Here also belongs the cataract of tetany. Diagnosis is not difficult because of the availability of the induced phenomena (Chvostek, Trousseau, Schultze? Erb, Hoffmann). The influence of tetany in maternity differs widely. Now and then premature labor is determined.

As a rule the child is born in good condition, but often enough the disease appears to have been transmitted. But even after the severest maternal tetany the infant may be perfectly sound without any suggestion of latent tetany. In certain cases the disease may appear in the first few days of life. The writer upholds the parathyroid theory, but knows of no pathogenic mechanism which applies to all cases. In certain women a goiter of pregnancy causes atrophy of the parathyroids. In animals removal of the parathyroids is followed by latent tetany which becomes active during pregnancy. In at least one autopsy case of maternity tetany the parathyroids, normal to the naked eye, were found to be the seat of extensive changes. Tetany must be ranked as a toxicosis which in certain respects resembles ergotism and points to definite chemical substances (amino-bases). However, the evidence is far from conclusive, and the author admits that we really know nothing of the nature of the poison. It appears to be certain that tetany is not a member of the pregnancy toxicoses. The known presence of normal parathyroids in tetany must be interpreted in favor of the existence of a second, extraglandular factor concerned with abnormal calcium metabolism which appears to act as a predisposition. It is easy to understand how this factor (deficiency of calcium) could be present in gestation and afterward. The treatment of maternity tetany does not differ from that of other forms.

Is an Increase of Birth Rate Desirable for Switzerland?—Goenner bases his article on one by Knopf of New York, who claims that birth control has its peculiar advantages in that it tends to diminish infant mortality, tuberculosis, lues and constitutional inferiority. It also favors early marriage and antagonizes illegitimacy. Knopf sees no shadows in such a state of affairs. He believes in a four-child system. In Holland this *modus vivendi* has obtained for decades, and despite the falling birth rate there is much less total mortality and child mortality. Mere falling off of birth rate is not necessarily an evil. The relative superiority in man power of Germany over France may have been a matter of birth rate, but inasmuch as it led to expansion of the former people it was directly responsible for the present war, for Germany's policy became one of peripheral expansion plus colonization. The increased birth rate has therefore reacted as a greatly decreased birth rate and increased mortality. Increased birth rate has brought Germany into conflict with almost the entire civilized world, and she had sustained only up to the first of 1917 a loss of births amounting to 1,177,000, with deaths from war mortality alone of 1,157,000. Her population had decreased by over 2,000,000 purely as a result of the war. These figures are given out by the Germans and may, of course, be censored. Under the most painful conditions imaginable the German mothers are now warned to make up this deficit. This can only lead to a vicious circle. Moreover, these mothers are actually asked to bear children to carry on a second war should the present one fail of victory. But the men who have fought this war rebel at the idea of more children who have no further outlook in life than munitions making and facing cannon. The mind that can think favorably of reproduction for such ends is abnormal, diseased. The problem has hit Switzerland already, and the Swiss women along the German frontier are shocked at the outlook. The republic is already overstocked with a population which can hardly be properly nourished. This is true now of the whole of Europe save Russia. In some Swiss cities the foreign element is outbreeding the native stock. The republic depends more and more on imports which help to feed its 700,000 aliens. Under such conditions should native women be asked to bear more children? The author is pessimistic about increasing birth rates by resolutions and recommendations. He believes in the existence of a great elemental reaction against high birth rates which is the outgrowth of rapid civilization and is essentially economical in character.

Hygiea.

November 16, 1917.

Enterocystoma.—Hansson has collected 48 cases of intestinal cysts from the literature and contributes a

personal observation. He gives a brief synopsis of the reported cases and discusses the question of pathogenesis. Studies of the embryos of seals made during the German South Polar Expedition of 1901-1903 finally determined that in the entire vertebrate division embryonal anlage of the pancreas are to be found throughout the intestine, as far down as the valves of Bauhin. The presence of cysts which protrude into the lumen of the intestine is better explained on this ground than any other. These cysts, together with those which develop from the omphalo-mesenteric duct, differ from all other forms of intra-abdominal cysts. The author's case ran the clinical course of an invagination and presented a strong resemblance to the well-known case of Sprengel in its microscopic structure. The cyst, which projected beyond the valve of Bauhin like a prepuce into the intestinal lumen, was seated between the two layers of muscle in the intestinal wall; and presented its own mucosa, which was atrophic, with villi but hardly any epithelia or glands. The cavity, which presented no communication with the intestine, was filled with cement-like substance.

Prophylactic Appendectomy Through a Hernial Sac.—Norrin reports a series of 81 cases of this form of intervention as performed by a number of Swedish surgeons. But 10 cases were in women, while the ages ran from 1 to 66 years. Over one-half were between 20 and 40 years. In 74 cases the hernia was right-sided, external inguinal, of which number 5 were incarcerated. In the majority the patients were operated on for such conditions as varicocele, hydrocele, retentio testis, hernia of the other side, etc. The operations performed were those of Bassini or Girard, and in all but a few cases primary union occurred. Sixty-six patients were discharged within 15 days' average. In all but 1 case the author noted the presence of macroscopic alterations of the appendix.

Finska Läkarsällskapets Handlingar.

September, 1917.

Unusual Indication for Cesarean Section.—Creutz of Engström's clinic reports seven cases of unusual indications for classical cesarean section. The first and second cases were in the same patient, who had a burdensome insufficiency of the public arch, fear of stretching the latter unduly and aggravating the condition led to the selection of the abdominal route. The third case was in a woman with placenta previa, who had weak pains widely spaced. The fetal heart sounds were irregular, and the head movable above the inlet. The cervix had not shortened nor was the os dilated beyond a finger's width. The membranes had not ruptured and patient's forces were already lessened. In Case IV the patient had a cardiac lesion, and total placenta previa. In Case V, in addition to pelvic stenosis, which alone would have furnished an indication, there was a strong suspicion of premature death of the fetus, verified by the results of cesarean section. Case VI occurred in a woman whose earlier gestations had terminated in death of the fetus—probably from premature detachment of the placenta. Cesarean section not only showed that the latter surmise was quite correct, but resulted in a living birth (unfortunately, the infant died on the following day). In Case VII the fetus was in a transverse position, with child still living. Cesarean section was regarded as the indication of necessity to save the child; version apparently offered no chance for its survival.

Fat Transportation in the Body.—Ehrström traces the fate of fat in the organism. It reaches the blood from the intestine, and is transported partly in the blood corpuscles and partly in the plasma. In the later it is present in solution, or as hemocones, or blood dust—in the latter state, chiefly after overconsumption of fat, or in disease (diabetes). Hemoconemia is a condition not well understood; in some sort it shows insufficiency on the part of the plasma to hold fat in solution. In health the fat content of blood is a relative constant, being slightly increased after eating fat. The red corpuscles also have their fat content somewhat increased, the corpuscular fat being transformed to lecithin. A hyperlipemia occurs *par excellence* in diabetes, but not always; more marked in severe cases, it may be absent in coma.

Book Reviews.

THE PRINCIPLES OF MENTAL HYGIENE. By WILLIAM A. WHITE, M.D. With an Introduction by SMITH ELY JELLIFFE, M.D., Ph.D. Price, \$2.00. New York: The Macmillan Company, 1917.

WHENEVER a book on psychoanalysis is placed before the thinking reading public, there accompanies it often a feeling of skepticism on the part of the reader as to the efficacy of the means offered through this channel for a solution of the same old problems which have disturbed the world for centuries. Only a small proportion of the medical profession, to say nothing of the general public, are believers in psychoanalysis. Holding the attitude "of the herd," we must all "be shown." Perhaps, in the main, this doubting attitude is a safeguard, for, as Dr. White says, no great work grows without effort; and the value of a particular movement is only increased, if it is worth while, by the amount of opposition encountered.

Mental hygiene has come to be one of the principal measures through which we may reach world betterment and eventual happiness; one of the measures toward personal understanding and hence toward personal happiness. One of its expressions is in psychoanalysis. Whether psychoanalysis is the final means in the attainment of improved mental hygiene, thus producing saner, broader social conditions and standards, is very far from being proved. It is, if anything, but one side of the broad prism of truth leading to other yet unknown means of understanding of human travail and human happiness. And all this preamble is but an introduction to a book which attempts to explain and offers a remedy by the psychoanalytic method for the social troubles of the mass of mankind which are the result of ill mental conditions. Dr. White covers the question of the criminal, the prostitute, the insane, the feeble-minded, the alcoholic, divorce, various types of the neuroses, and even the woman movement. He gives much thought to the humane treatment and understanding of the insane, criminal, and the feeble-minded. He also shows how far away we are from the goal of complete understanding of these and other abnormal conditions afflicting humans. The reader may not always agree with the author in his solutions, but, agreeing or not, he will find in this book a hopeful, broad-minded, uplifting attitude and outlook toward all of these questions which have troubled mankind so long. The book has much to offer to the men of the law, physicians, social workers, and every intelligent reader who is eager for a better understanding of the problems of life in their human aspect, and with a desire to improve social conditions by an improvement of the individual. "Each individual would need individual treatment—the principle for which this book stands."

RECOLLECTIONS OF A NEW YORK SURGEON. By ARPAD G. GERSTER, M.D. Price, \$3.50. New York: Paul B. Hoeber, 1917.

THIS book deserves reading by far more than the author's very large circle of friends and acquaintances, although to these, of course, it will especially appeal. It is essentially an autobiography and as such is unlikely to have the extensive circulation which it deserves on the basis of its real literary merit and the real interest which it cannot fail to excite in the reader, absolutely irrespective of whether or not he may have the good fortune to be personally acquainted with the author. Gerster's personages are real, many, like Billroth and Zorn, being of world-wide renown, and he describes real situations, real places and real peoples.

Gerster divides the book into three parts: The first, covering his life in Europe; the second, his emigration and life in this country; the third, his diversions. There is also an Appendix covering certain miscellaneous matters, including the list of his publications and the list of offices and memberships held. Finally, there is an exceptionally good index. The reader cannot fail to enjoy accompanying the author through his school and university days and noting the various points of similarity to or variance from the experiences of his own school and college life. One must admire the courage with which Gerster set out from home determined to succeed in his chosen profession in a strange

land thousands of miles away. The story of his journey and the trials and successes of his early years in this country should be inspiring to any young man who contemplates entering the medical profession. But the young man who reads this book even superficially cannot fail to recognize the fact that Gerster's ultimate success was based not alone upon fortuitous circumstances and the happy faculty of making friends who would interest themselves in his advancement, but also and fundamentally upon years of conscientious study, attention to detail, and hard and painstaking work. How many, while in the throes of building up a practice, would devote spare time for almost a year to the systematic study of Greek grammar, as did Gerster, and still bewail not being able to read Homer as fluently as Virgil? Or when in the midst of an unusually busy hospital and private practice would still find time for the serious study of music, drawing and etching? One cannot read far in this book without realizing that besides being endowed by nature with the capacity and desire for the acquisition of knowledge the author has been an indefatigable worker from youth to the present day. Hence one cannot wonder that the ambitions of early manhood have been abundantly realized, and that besides many lesser honors the author has been the recipient of the highest honor in the gift of perhaps the most expert body of surgeons in the world—the presidency of the American Surgical Association.

PRACTICE OF MEDICINE. A Manual for Students and Practitioners. By HUGHES DAYTON, M.D., Associate Attending Physician, New York Hospital; Attending Physician, Hudson Street Hospital; Formerly Instructor in Physical Diagnosis, Cornell University Medical School, New York. Third revised edition. Price, \$1.50. Philadelphia and New York: Lea & Febiger, 1917.

THIS volume can be characterized as the smallest work on the Practice of Medicine. It is the third edition of what first appeared as an "epitome." Within the compass of about 300 small pages the author has ventured to compress the "Practice of Medicine." It is true that space has been gained by the omission of diseases of the pharynx, larynx, and tonsils, as well as nervous and mental diseases; but, even so, diseases of the importance of acute poliomyelitis, syphilis, and gonorrhea cannot be properly treated in the space of one page or less. One line, or less, is devoted to the diagnosis of secondary anemia, the treatment of cardiac hypertrophy, the pathology of hydrothorax, and of acute poliomyelitis. The little that there is is so well done that it is a pity the author does not write a complete "Practice."

CONGENITAL WORD-BLINDNESS. By JAMES HINSELWOOD, M.A., M.D., F.R.F.P.S., Glasgow; Late Surgeon to the Glasgow Eye Infirmary and Lecturer on Ophthalmology in the Glasgow Western Medical School. Price, \$4. London: H. K. Lewis & Co., 1917.

THE author of this handy little book will at once be recalled as having contributed so much to the subject of aphasia before and since his book on letter-, word-, and mind-blindness in 1900. That congenital word-blindness is much more frequent than is generally supposed and has a better prognosis should be known to all physicians, especially those who examine school children, and thus many such might be saved from life-long illiteracy. Dr. Hinshelwood has presented his subject in a concise but thorough manner.

THE SURGICAL CLINICS OF CHICAGO. Volume I, Number 5, October, 1917. Octavo of 216 Pages with 84 Illustrations. Published Bi-monthly. Price per year, \$10. Philadelphia and London: W. B. Saunders Co., 1917.

THIS number contains reports of the clinics of sixteen Chicago surgeons, and the material presented is particularly varied in character. Mock's report of a case of bichloride of mercury poisoning diagnosed as, and operated on for, perforated gastric ulcer is of especial interest. Bevan's discussion of breast tumors; Harris' case of hernia of the breast; Andrews' case of hemangioma of the brain, inoperable by ordinary methods and treated by boiling water injections and the hot metal point; Carl Beck's case of elephantiasis treated by the Handley operation; and Eisendrath's discussion of the complications of appendicitis deserve especial mention.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 20, 1917.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THE program of the evening was presented with the cooperation of the Section on Laryngology.

The Treatment of Stenosis of the Larynx and Trachea Following Diphtheria.—Dr. HENRY LOWNDES LYNAN read this paper, which he illustrated with lantern slides. He classified stenosis of the larynx following diphtheria according to its causation into four types as follows: (1) Neurotic, (2) Spasmodic, (3) Traumatic, (4) Pathological. In considering the first group he said there was a marked neurotic element which accompanied all cases of acute and chronic laryngo-tracheal stenosis. The impending fear of having an intubation tube removed or a tracheal cannula changed promoted a stage of excitement often bordering on convulsions, especially in children. The passive congestion caused by the crying or struggling of the child added to the difficulty and invariably made reintubation or recannulation necessary from glottic spasm, and subglottic and tracheal edema. At times adults suffered from this "neurotic shock" in equal proportion to that encountered in children. As it was so much easier for the child to breathe through the properly fitted intubation tube or tracheal cannula, the fright that followed, when the intake of air was to them not so easy as with the tube *in situ*, often made detubation and decannulation extremely difficult. There was apparently a vicious circle which should be considered with this "chronic neurotic fear" of impending accident. Venous passive congestion promoted subglottic edema and gradual asphyxiation, and the fear of asphyxiation kept up the ever active neurotic element. All of these conditions taken together made the final cure of the case at times an extremely discouraging problem. (2) Glottic spasm was usually the result of the wearing of an intubation tube for a long period, especially when the neck of the tube was too thick and held the vocal cords in a state of fixation or functional disuse. The wide neck intubation tube virtually acted as a splint to the intralaryngeal muscles, and as the balance of power between the opposing two sets of muscles, the adductors and abductors, was disturbed adductor spasm was the natural result. Supraglottic and arytenoid edema might or might not contribute to this rapid closure of the glottic aperture. To overcome pure spasm of the adductors an extremely narrow necked tube with a long anteroposterior lumen should be used to allow for reeducation of the posticus muscle and give the cords a chance to separate. The speaker had overcome glottic spasm in a number of cases by the use of the flat head and cut-out abductor tubes. In other cases upon whom digital intubation had been constantly performed he had been able to deceive the patient by removing the tube by direct inspection and immediately introducing a small tracheoscope or bronchoscope between the cords and then gradually removing the tracheoscope, and he was thus able to see the partial separation of the cords on inspiration. These patients who had become accustomed to the digital method of the removal of the tube were not aware of what was being done when the tube was removed by direct means and hence the neurotic element was overcome. The cut-out flat tubes should never be used when there was polypoid tissue present. Practising deception as a cure for adductor spasm with a tracheoscope was of no use in supraglottic or subglottic edema. Tracheotomy as recommended by Dr. Jackson would also overcome the spasm with gratifying results. (3) Under this heading of traumatic came the unfortunate false passages made in the larynx by the hand of the unskilled intubator. It was not infrequent when examining the larynx by direct inspection to see the hole which had been driven into the laryngeal ventricle, or a fracture of the cricoid cartilage and dislocated arytenoid, or both. The attempt at digital intubation had been made at times with such force that the end of the tube was driven

through the cartilage out into the tissues of the neck. The making of a false passage in these days of direct laryngeal intubation was inexcusable. Far less damage would be caused by a tracheotomy even when not performed in the median line than by one attempt at intubation when an effort was made to drive the tube in at all hazards. Dense cicatrices had followed laryngofissure operations for the removal of so-called bands of adhesions when the wound was allowed to granulate over an intubation tube. Another type of traumatism might result from a rapid stab tracheotomy when pieces of the trachea had been sliced off, more than one tracheal incision made, or as the result of thyrotomy and tracheotomy. Again there might be injuries as the result of tracheotomies in the autoextubation stage when there had been extensive destruction above the cannula at the cricoid level. All of these traumatic and surgical measures greatly contributed to the development and prolongation of laryngeal stenosis. (4) The entire pathology of laryngeal stenosis was laid down in the beginning with the acute diphtheritic process, the amount of laryngeal involvement as well as the amount of traumatism at intubation. Under this heading one might have hyperplastic and cicatricial types which might be supraglottic and subglottic. The hyperplastic and cicatricial types were both supraglottic and infraglottic. The supraglottic type was usually due to marked edema occurring at the base of the epiglottis and ventricular bands. After the removal of the intubation tube the edema might greatly increase and close the laryngeal orifice. This type might also be due to polypoid supraglottic connective tissue masses falling together and closing the laryngeal lumen immediately on the removal of the tube. Among other pathological types which the speaker discussed were decubitus ulcers, paralysis, perichondritis, chondritis, metaplasia, and endochondrial bone formations. When there was marked edema of the arytenoid cartilages it was best to leave the tube in place, for the arytenoids and aryepiglottic folds would close over the glottic opening and shut off attempts at respiration. When the edema was confined to the subglottic level the edema was not so rapid and the child might breathe for a short time without the tube. Polypoid masses of new connective tissue sometimes arose from the epiglottic base and ventricular bands. These masses, when not recognized by direct means, fell together as soon as the intubation tube was removed and obstructed inspiration. They were easily removed with the guillotine or punch forceps and when cauterized did not recur. Decubitus ulcers might result from the moving to and fro of the intubation tube, and when of sufficient depth involved the perichondrium and chondrium of the cricoid cartilage and soon the tube was autoextubated. If the pressure continued or larger and larger tubes were introduced to prevent autoextubation further damage might result leading to a complete necrosis and disappearance of the cricoid cartilage. The essayist said that while he was willing to admit that all tracheotomies arrested the larynx they would not arrest the formation of new connective tissue and the complete atresia of the larynx and trachea above the cannula was the inevitable result. All of the cough-up cases should be treated early with the author's bulbous tracheal noncough-up tubes, as these tubes put an absolute stop to autoextubation. They also saved much anxiety, as one could leave the patient and feel perfectly comfortable. They were far preferable to the tracheal cannula and had a tendency to keep the larynx open and to rest it at the same time. Paralysis of the motor nerves of the larynx in diphtheria seldom, if ever, occurred. In over 100 cases of all forms of multiple neuritis following diphtheria, in whom no intubation was performed, direct inspection showed no paralysis of the motor nerves. On the other hand, the superior laryngeal nerve was affected in a small percentage of cases. The result was an inability to cough out secretions which made respiration difficult and caused a damming back of the secretions in the bronchi and lungs with a consequent pneumonia or drowning in their own secretions. This was the invariable result, especially in young children. One might have a metaplasia of the thyroid and cricoid

cartilages from the long continued inflammation, resulting in new cartilage formation which extended out into the lumen of the larynx. Perichondritis or chondritis might follow decubitus or tube pressure sores caused by the retention swell of the tube in the cricoid level. Von Bokay in his work on intubation claimed that the pressure of the tube on the recurrent laryngeal nerve caused the coughing out of the tube. This, however, Van Gieson and the speaker had found to be incorrect, for the recurrent laryngeal nerves as they entered the larynx were perfectly normal histologically, and the true cause of the coughing out of the tube was the perichondritis and chondritis at the cricoid level. Perichondritis and chondritis might also involve the arytenoid cartilages and the cricoarytenoid joint and there might be fibrous, metalplastic, or bony ankylosis of this articulation, rendering the vocal processes and ventricular bands immobile. Endochondrial bone development occurred as the result of perichondritis and chondritis. The bony spurs might grow directly into the larynx, making the case extremely difficult to cure. The method of getting rid of the spurs was to cut them off, cauterize the surfaces and introduce the intubation tube into the larynx. Dr. Lynah described a rubber-covered cannula which was effective in preventing the formation of granulations and cicatrices.

Dr. JOHN ROGERS said it was a great satisfaction to hear Dr. Lynah say that practically all cases of laryngeal stenosis following diphtheria could be cured if treated along the lines that he had marked out. He had become interested in this subject some fifteen or twenty years ago and must confess that he had very few cures in the beginning of his work. He had at first tried excision of the cicatrices but found that not many cicatrices were permanently removed by this procedure, and frequently something worse developed than the condition for which he had operated. In fact, many of these cases lost a large part of the thyroid or cricoid cartilage. It was interesting to hear Dr. Lynah say that the same thing had happened in a number of his cases, and that these cartilages would regenerate and he had shown specimens demonstrating that the cartilages did reform. In the speaker's fifteen or twenty years experience with these intubated cases of laryngeal stenosis, it was interesting to follow the outcome after a number of years had passed. He had just last month received a letter from one of his earlier patients who had now reached young manhood. This former patient began his letter by thanking the speaker for what he had done for him and saying that his voice had made a nearly perfect recovery; in this case there had been a large slough of the cricoid. This young man had so far recovered his voice that he wished to study for the ministry. Another patient was a Vassar student who, since her graduation, had been teaching a subject requiring the almost constant use of her voice and she suffered no inconvenience from her former laryngeal trouble. All of these cases were handled as Dr. Lynah advised, namely, by long continued dilatation. Adults were much more difficult to manage than children, and adults with intubation for chronic stenosis were more liable than children to develop pneumonia. Dr. Rogers said that quite early in his experience with these cases he was impressed with the danger of autoextubation, and to escape this complication he devised a so-called "plugged tube". It was an instrument with a right-angled attachment, or "plugs," which after the intubation tube was in place was pushed through the usually present tracheotomy fistula and screwed or fastened at a right angle into the intubation tube. Dr. Lynah seemed to have improved on some of the earlier instruments which were occasionally quite troublesome, though indispensable to the patient. The "plugged tube" for these autoextubation cases had to be worn for many months before the hypertrophic laryngitis, usually present and apparently causing the autoextubation, had subsided. The fistula then usually closed spontaneously, or after a freshening of its edges; but during this period and for some time afterwards, he had generally instituted the wearing of an ordinary intubation tube with a large enough neck to prevent undue cicatricial contraction. This little device was sometimes difficult to manage, and occasionally unsatisfactory, and to make required expert workmanship, but

on the whole he had found it useful. Dr. Rogers, in closing, congratulated Dr. Lynah on his excellent results, and expressed the hope that this method of treating all forms of chronic laryngeal and tracheal stenosis would speedily be recognized as the best.

Dr. EMIL MAYER said it was almost impossible to say much to the laryngologists who saw the ultimate results of these cases, whereas he saw these cases as a rule almost immediately after infection had occurred. To the laryngologist these cases came as a stenosis, and happily they came much less frequently than in the earlier days when Dr. O'Dwyer was still with us and showed us how to perform intubation. Recently these cases seemed to have become still less frequent so far as the laryngologist was concerned. It should be remembered, however, that diphtheria was not the only disease that might be followed by stenosis of the larynx. It had been known to follow typhoid fever. He thought he might epitomize briefly by saying first and foremost: "Do not do any external surgery in stenosis of the larynx. Remember that the larynx is extremely tolerant of endolaryngeal methods of treatment." One might use even an ordinary uterine dilator followed by the introduction of a large intubation tube. Dr. Mayer said he was sorry to hear Dr. Rogers speak so disparagingly of his rectangular apparatus for preventing autoextubation. He did not think he did himself justice. One more point he wished to mention and that was that they should give the patient time to recover; if given time these patients would recover, though it sometimes took a long while. He knew of nothing that could be done for those suffering from this condition other than to follow out the patient and long-continued treatment recommended this evening.

Dr. WILLIAM P. NORTHRUP referred to his association with Dr. O'Dwyer in his early work on intubation. He stated that Dr. O'Dwyer had invented the tubes and was the first to use them both in the hospital and outside. While Dr. O'Dwyer was engaged in perfecting the tubes and putting them in, the speaker was making the autopsies and digging the tubes out. Dr. Dillon Brown had practice in doing the intubations in the hospital and later outside. The speaker was the pathologist. The others had passed on and hence he was the oldest living person associated with this early work in intubation. Many modifications of the O'Dwyer tubes had been made but the principle still stood. Dr. O'Dwyer was five years in perfecting the tubes and when he had finished them and they were ready to be put on the market there was only one change made, and that was in the gag; instead of twisting down as Dr. O'Dwyer first made it, it went straight back. Dr. Dillon Brown was a very skillful operator and Dr. O'Dwyer of course was. Dr. Northrup said he had had 125 cases of his own and he did not recall one instance in which the intubation tube was retained. He had asked Dr. Lynah why it was that he had so few retained tubes and Dr. Lynah was now getting so many. Dr. Lynah's answer was quite satisfactory. He said that the cases in the speaker's series were either in private practice where they were seen early or they were in the hospital where they were seen still earlier. The difference was due to the cases themselves. The patients in which they had unsatisfactory results were either poorly nourished, or they were seen late, or the membrane was below the vocal cords. Dr. Northrup related his experience with tube cases before the days of antitoxin, stating that he frequently had several cases with tubes in at the same time and that it was no easy matter to keep a watch on a number of cases widely scattered throughout the city. Dr. O'Dwyer's great achievement was his insertion of the tube and making it fit anatomically into place; his second great achievement was intubation for chronic stenosis due to syphilitic lesions of the larynx. A third problem that Dr. O'Dwyer was working on at the time of his death was how to retain the tube so that it would not be coughed up. He had worked this problem up and had partly prepared the results of his work for publication at the time of his death, but it was never published. Dr. Northrup also referred to the part Dr. William Kelly Simpson and Dr. Clinton Wagner had played in developing the work that Dr. O'Dwyer had initiated.

Dr. D. BRYSON DELAVAN said that the address of the evening should touch the civic pride of all present. It should be recalled with satisfaction that the principles underlying the treatment of chronic stricture of the larynx had been first discovered and applied in New York City and that their development had been carried out by New York men. Horace Green, a founder of the Academy of Medicine, was the first to recognize the important physiological fact of the tolerance of the larynx to the presence of a foreign body. Joseph O'Dwyer, going a long step in advance, successfully demonstrated the tolerance of the larynx to the continued presence of a foreign body. Following his own discovery, O'Dwyer perfected the art of intubation for the relief of acute laryngeal obstruction. Later he entered upon the study of the cure of chronic cicatricial stricture of the larynx and trachea. Something had already been accomplished in the successful treatment of cicatricial webs of the larynx by dilatation, or by cutting of the web, followed by dilatation, by such methods as those of Morell Mackenzie, Whistler, Schroetter, Gleitsmann, and others, and the operation of thyrotomy for the deeper and more diffused strictures had been successfully practised and perfected by Clinton Wagner. But by the above methods of dilatation the stretching of the scar tissue was not very vigorous and it could only be applied at intervals and for a few minutes or less at a time. O'Dwyer thought that dilatation, to be effective in the more stubborn cases, must be applied by means of a dilator made of hard, unyielding material and that the stretching at the cicatricial bands must be maintained at a maximum and continuously for long periods of time. O'Dwyer died before he had perfected the execution of this idea. Subsequently Dr. John Rogers undertook to elaborate it. The success of his efforts was complete. For certain types of cases his method had not been surpassed, permitting as it did continued forcible dilatation of the constricted areas with a minimum of discomfort to the patient, with perfect security in the retention of the tube, and without further external operation in cases in which a tracheal cannula had already been worn. The value and effectiveness of this method was far greater than Dr. Rogers had led them to suppose. Much time and patience must sometimes be used in its application, but with these a far greater degree of ultimate success could often be attained than by the use of harsher means. Not seldom a good thing had been lost or else set aside and forgotten. With Dr. O'Dwyer time had only added to the world's appreciation of his genius and to the value of his great original ideas. Thus, in 1913, a tablet was set up in the diphtheria department at the Stephania Children's Hospital in Budapest in honor of Dr. O'Dwyer and in commemoration of the performance of 2000 intubations in that institution. Far in advance of anything done abroad, Dr. Lynah had continued the good work of Drs. O'Dwyer and Rogers until there were few cases, however difficult, which were not amenable to relief at his skillful hands, while his demonstration had been so clear and graphic as to make his methods readily understood. Gurden Buck, the father of intralaryngeal surgery, Horace Green, Clinton Wagner, John Rogers, and the lecturer of the evening were all citizens of New York and members of the Academy of Medicine, a fact of which as Fellow members we had abundant reason to be proud.

Dr. HENRY L. SWAIN of New Haven believed that the answer to Dr. Northrup's question as to why he saw so few cases of retained tube and Dr. Lynah saw so many was that severe cases came in waves. In New Haven, at the Contagious Disease Hospital, they had no cases of retained tube for two or three years until a month ago when four occurred all at the same time. He had had no cases of tracheotomy for a long time and then four occurred at the same time, simply showing how these cases ran in waves. The demonstration of the evening hinged on the development of the work of Dr. O'Dwyer by the use of the direct laryngoscope. Dr. Lynah had shown that the bronchoscope and direct laryngoscope could be used in cases of acute stenosis. The audience was to be congratulated on such a demonstration.

Dr. L. T. LEWALD said he just wished to voice his sentiments in regard to Dr. Lynah's work since he had

had the opportunity to control it by roentgenographic examinations demonstrating the cures in these cases. He had been struck by Dr. Lynah's persistence and care in following up these cases. In regard to one of the cases shown, the case of bronchiectasis of the upper lobe of the lung, that case was of considerable interest as it was the only one of posterior bronchiectasis in the upper lobe that he had seen, and the recovery as shown by the x-ray in that case was remarkable. The relation of enlargement of the thymus to the laryngeal stenosis was interesting. In one case the treatment of the thymus gland by the x-ray had led to so much improvement that he was forced to believe that the pressure of the thymus did much to keep up the irritation and stenosis of the larynx.

Dr. LYNAH, in closing, commended the work of Dr. Rogers, whose method of cannulation, while following the principle of that of Dr. O'Dwyer, was an improvement upon it. Formerly when there was any trouble with the laryngeal tissues resulting in the formation of scar tissue, perichondritis, chondritis, or metaplasia, they had operated and attempted to get rid of the tube. They now obtained very excellent results by the frequent dilatation of the stenosis in these cases, thus going back to the original idea of O'Dwyer. Dr. Lynah said his personal experience was that the voice was better in the cases treated by intubation and successive dilatation than in those treated by laryngotomy. It might be recalled that he had shown several cases before the Laryngological Section last year with normal speaking voices following prolonged intubation. It was remarkable what the larynx would tolerate in the way of dilatation and internal treatment, yet occasionally one met cases that were very refractory and discouraging. Dr. Swain spoke of the severity of the cases as a factor influencing the results of intubation. He thought Dr. Swain was correct, for he had seen cases in which properly fitting tubes were used and the technique correctly carried out, and nevertheless complications ensued which were probably due to the severity of the original diphtheritic infection. Dr. LeWald had been making the x-ray pictures and had shown some remarkable instances of the influence of an enlarged thymus upon laryngeal affections. Dr. LeWald reported that after an appropriate course of treatment the enlargement of thymus in these cases had almost disappeared.

SECTION ON SURGERY.

Stated Meeting, Held November 2, 1917.

Dr. JOHN DOUGLAS IN THE CHAIR.

Congenital Pyloric Stenosis.—Dr. W. G. VINCENT presented this case for Dr. EDWARD W. PETERSON. He stated that the child was born in the Jewish Maternity Hospital, in February, 1916, and weighed 5½ pounds at the time of birth. The child did well for ten days while it was in the hospital. On the third day after its return home it began to vomit with more or less frequency. The vomiting became persistent and the child presented the classical symptoms of pyloric stenosis, projectile vomiting and marked visible peristalsis. The urine was scanty and the child hungry. A tumor mass about the size of an olive could also be detected. It was decided that operation was indicated. The Rammstedt operation was performed and in this connection the danger of the pyloric incision perforating the duodenal junction with the pylorus should be borne in mind. This accident occurred in the present instance but the duodenal puncture was closed with one stitch and all went well with the patient. Hyperdermoclysis was employed at the time of the operation. Dr. Peterson gives intravenous saline by injecting it into the superior longitudinal sinus. The child did well until recently. The x-ray now showed hypomotility of both the stomach and intestines.

Carcinoma of the Orbit, Cheek, and Superior Maxilla; Result of Operation.—Dr. GEORGE H. SEMKEN presented this case. He stated that this patient, a man 61 years of age, a teacher of languages in a western university, came under his observation in June, 1917. The origin of his malady dated back to 1907, when an epithelioma

began in a cicatrix in the upper right cheek. The cicatrix had been produced by the electrolytic destruction of a small angioma. The epithelioma was excised in 1907. It recurred in 1910, when it was apparently cured by x-ray treatment administered by Drs. Hill and Thomas of the Lakeside Hospital Staff in Cleveland, Ohio. The second recurrence, in 1912, was treated in the same way, with a similar result; but the third recurrence, in 1915, was uninfluenced by this method, although given by the same competent roentgenologists. On July 17, 1915, the growth was removed by operation, which included apparently the scraping of the lower bony orbital margin and the use of the actual cautery. The last recurrence was about November, 1916, when the x-ray was again tried but proved unsuccessful. At the time the patient came under the speaker's observation, in June, 1917, he had a small deep area of ulceration over the lower bony margin of the right orbit, around which there was an area of induration in the cheek tissue adherent to the orbital margin. There was pronounced ectropion of the lower lid, with injection of the palpebral and lower bulbar conjunctiva. The movements of the eyeball seemed unrestricted, but there was a slight protrusion and displacement of the eye. The patient had double vision. There was no visible or palpable extension of the process to the nasal cavity or through the hard palate. There was no demonstrable involvement of the glands of the neck. The operation was performed at the New York Skin and Cancer Hospital, in June, 1917, under ether-colonic anesthesia. The operation was briefly as follows: (1) As a preliminary step, the right common carotid artery was exposed and an untied catgut ligature was placed about it so that hemostasis could subsequently be produced if necessary. (2) For the removal of the tumor an incision was made through the upper right eyelid, just below the eyebrow, from one end to the other. It was carried down the side of the nose, then across the cheek, two or three cm. below the lower limit of the neoplasm, and finally upward at the outer end, well external to the eye, to join the upper lid incision. The incision was deepened to expose the outer and upper orbital margins, the nasal process of the superior maxilla, the lower antero-external surface of the upper jaw, and the outer part of the malar bone. The malar bone was divided at its outer end with the chisel, and a similar section was made through the outer orbital wall, from before backward. The radical exenteration of the orbital contents, with the straight raspatory, was done from above downward, the optic nerve and vessels being cut well back, with scissors. Next followed the division with the chisel, of the nasal process of the superior maxilla and the adjacent inner orbital wall as far as the sphenoidal fissure, and in succession, the antero-external wall of the superior maxilla, above the incisor and canine teeth, the alveolar process through the region of the first tricuspid, and the hard palate from this point obliquely backward and inward. The tumor could then be removed en masse. Finally the invaded posterior ethmoid cells and the partly eroded upper bony lateral nasal wall were removed, and all the tissues that had been close to the area of the neoplasm were destroyed by the actual cautery. (3) The wound was closed with the frontal flap. The large resultant cavity was loosely packed with five per cent. iodoform gauze. The external closure was then accomplished by means of a large flap of skin and subcutaneous fat tissue taken from the forehead, having its pedicle at the lower temple region and its apex mesial. It contained the uninjured temporal artery and veins. The site from which it was taken was covered with Thiersch grafts. Healing had been uneventful. All of the Thiersch grafts took. Since the operation there had been a progressive obliteration of the cavity. As an added precaution against recurrence this patient had had intensive treatment with radium by Dr. H. H. Jane-way on July 12, 1917, and milder treatments on November 1 and 2.

Cases Illustrating Surgical Treatment of the Lesser Curvature.—Dr. A. J. BELLER presented six cases illustrating the six types of surgical treatment of the lesser curvature, namely, sleeve resection, partial gastrectomy with gastroenterostomy, excision, excision with gastroenterostomy, excision with jejunostomy, and jejunostomy.

Tuberculous Peritonitis, Saddle Ulcer of Lesser Curvature; Carcinoma of Stomach; Colonic Bands.—Dr. SETH M. MILLIKEN presented this patient. He stated that the history of this patient was briefly as follows: She was 22 years of age at the time of her first operation, on December 20, 1907. The operation was performed for the relief of a tuberculous peritonitis. A low incision was made and a small amount of yellow fluid was obtained. Small tubercles were found along the lower margin of the omentum and along the mesentery. The abdomen was cleansed as thoroughly as possible and closed. After this the patient made an uneventful recovery and remained perfectly well until 1913. She was then admitted to the medical division of Lincoln Hospital. After observation it was decided that she had a surgical ulcer. She was operated on in June, 1914, when she was run down almost to the starvation point. It was found at operation that she had a saddle ulcer of the lesser curvature proximal to the pylorus and involving both the anterior and posterior walls of the stomach. The operation consisted in a sleeve resection and the removal of approximately one quarter of the stomach. The patient improved rapidly, her weight going up to 132 pounds, and she was able to work as a waitress for the following two years. Last year she had a recurrence and suffered from return of symptoms from December to June of this year. The x-ray showed a large pouch in the cardiac end and a shadow the shape of a finger along the pyloric end of the stomach. The x-ray plates taken after a bismuth injection show two kinks at splenic flexure of the transverse colon. The patient not only had tympanitis, but there was a ball on the lower right side that would form and then gradually fade away. The patient was in extremely bad condition, weighing only 75 pounds just before operation. At the exploratory operation a mass was found involving the entire distal half of the remaining stomach and firmly adherent to the pancreas and under surface of the liver. A long loop anterior gastroenterostomy was done as high up as the operator could reach on the cardiac end of the stomach. It was found that there were two very dense bands extending across the distal one-half of the transverse colon, apparently scar tissue bands. These bands were released and the wound closed. The patient made a surprisingly good recovery. She spent five weeks at the Burke Foundation Convalescent Home, where she gained twenty pounds. She now weighed 105 pounds and was back at work. The pathological examination showed the condition to be carcinoma as shown by glands removed for microscopic examination.

The Roentgenological Diagnosis of Congenital Pyloric Stenosis.—Major LEON T. LEWALD said he had been studying this subject since 1910, and had been very much impressed with the definiteness with which one could differentiate a pyloric stenosis from other conditions and decide whether a case was suitable for operation or not. It had been interesting to see how this subject had developed. Men were rather doubtful as to the value of the x-ray in the diagnosis of pyloric stenosis, but each man as he got a case and saw what roentgenology revealed became enthusiastic in its praise. In this way most of the men who had grown up in the x-ray work had learned what it could teach them in the way of diagnosis. He did not wish to give the impression that he would have the x-ray take the place of other methods of diagnosis; it yielded the best results only when accompanied by all the data that could be secured. He would prophesy, however, that the time was coming when every patient suspected of having a pyloric stenosis would be given a roentgenological examination, just as every surgeon today had an x-ray examination made in every case of fracture. Major LeWald then gave a lantern slide exhibition showing first different types of normal stomachs in infants and said that in infancy there was a great variation in the size and shape of stomachs that might be considered normal. He then showed slides illustrating pyloric stenosis and the conditions before and after the operation of gastroenterostomy. These showed that gastroenterostomy might result in a too rapid emptying of the stomach. The Rammstedt operation did not possess this disadvantage. The only disadvantage of the Rammstedt operation was the danger of puncturing the duodenum. He had known this accident to occur but

the opening was sewed up and the patient did well. He felt convinced that the Rammstedt operation was to be given the preference in operating on pyloric stenosis in infancy.

Clinical and Experimental Studies of Congenital Pyloric Stenosis.—Dr. RICHARD LEWISOHN presented this communication, in which he expressed the opinion that the division of cases of congenital pyloric stenosis into groups was too didactic. Holt's advice simply to divide these cases into mild and severe was more in accordance with the clinical facts. He did not agree with the viewpoint expressed by different authors that all patients with congenital pyloric stenosis should be operated upon immediately. The pediatricist ought to try to cure these cases with proper regulation of diet, paregoric, etc. If his attempts were futile and the baby was losing weight rapidly, the case should be treated surgically without delay. The essayist analyzed a series of 16 cases of pyloric stenosis admitted to Dr. Koplik's service at Mount Sinai Hospital during the last three years. Eight of these were treated medically and eight were transferred to the surgical department. Of those treated medically one died and seven were discharged from the hospital improved or cured. Of the eight cases operated on four were cured and four died. The Rammstedt operation, consisting of incising in a longitudinal direction the thickened and hardened pylorus through the serosa and muscularis down to the mucosa without opening the latter, the one most generally adopted in the surgical treatment of pyloric stenosis in infants, was employed. The essayist described the microscopical findings of sections removed from the center of the incision at the seat of operation in a fatal case and from the proximal and distal ends, and stated that these sections demonstrated very plainly the incomplete division of the muscularis. In order to avoid the danger of perforation, the incision had been a concave one and the stenosis was thus not completely relieved. While the apparent simplicity of the technic of the Rammstedt operation was likely to appeal to every surgeon, it was not as simple and safe a procedure as had been claimed by Rammstedt and other surgeons. The operative mortality of 13 per cent. among 36 gastroenterostomized cases (combined statistics of Scudder, Stillman, and Richter) compared favorably with the mortality of 24 per cent. in Downes' cases following the Rammstedt operation. It would require a much greater series of cases than had heretofore been published before a decision could be reached as to whether the Rammstedt operation could be considered the method of choice or whether gastroenterostomy, though less rapid in its execution, might not give better clinical results.

Dr. WILLIAM A. DOWNES said he had performed 100 Rammstedt operations for hypertrophic pyloric stenosis, and the more he saw of this operation the more he was convinced that it should be given preference over gastroenterostomy. When the operation first appeared he was prejudiced against it. He performed it once and then returned to gastroenterostomy. He then lost several gastroenterostomies by persistent vomiting and diarrhea coming on six or seven days after the operation, so he returned to the Rammstedt operation. In his series of 100 cases there were twenty-one deaths, and out of the twenty-one fatal cases eight or nine would have been hopeless by any operative procedure. Only one case was refused operation, and that was a baby weighing three pounds and two or three ounces, and practically dead when brought to the hospital. He had operated upon a number of babies that were almost in collapse. They were transfused, operated upon, and made good recoveries. He felt that one was scarcely ever justified in refusing to operate on any case of pyloric stenosis however bad the condition. After the Rammstedt operation he had lost two babies from hemorrhage; one of these was a hemophilic and the other bled to death from an unclosed vessel. One accident that must be borne in mind was opening the duodenum. In passing from the thick musculature of the pylorus to the thin tissue of the duodenum there was danger of penetrating the latter. This accident had occurred four times in his experience. The puncture was easily repaired, but one of these babies died of peritonitis about ten days after the operation. In about twenty cases a sound was passed through the pylorus to dilate the open-

ing by means of a small incision in the anterior wall of the stomach some distance from the pylorus. The benefit was doubtful and did not seem to justify the added risk. Among the twenty-one deaths occurring in this series of cases there were several due to enterocolitis which occurred from ten to thirty days after operation, but which were counted as operative deaths. Dr. Downes said he had compared the postoperative course of infants after gastroenterostomy and after the Rammstedt operation, and he felt convinced that they made a more straightforward convalescence after the Rammstedt operation. Even a few hours after operation they would have improved considerably and would want food, and they did not show the tendency to develop diarrhea and vomiting that was sometimes seen after gastroenterostomy. Dr. Downes also cited evidence showing that the results obtained by the Rammstedt operation were permanent.

The Surgical Treatment of Ulcer of the Lesser Curvature of the Stomach.—Dr. ALBERT A. BERG made this presentation. He said that while many different methods had been devised for the surgical treatment of ulcer of the lesser curvature, the surgeon when confronted by a given case was still in a quandary as to what surgical procedure he had best employ—which one would be followed by the best distant as well as immediate results. He said that he wished to discuss this subject not only from the standpoint of the operative procedure but from that of physiological function and a study of the musculature and nerve supply of the stomach. Surgeons were pretty well agreed that for an ulcer on the lesser curvature near the pylorus pyloroplasty was the operation of choice, but if one excluded these ulcers near the pylorus and those in the extreme cardiac end of the stomach then there were many moot questions. First with reference to the muscles and nerve supply of the stomach, there was no accurate description of the nerve supply of the stomach. Hence the statements that he would make were based largely on clinical observation rather than upon anatomical demonstration. All the peristaltic waves started at the reentrant angle between the vertical and horizontal parts of the stomach. There was no definite connection between the Auerbach's and Meissner's plexus and the nerve supply of the stomach itself. The initiation of the peristaltic waves was derived from the relay center in the reentrant angle; hence if this was removed the musculature of the stomach became paralytic and one had clinically a condition of the stomach similar to paralytic ileus. Excision that included the relay nerve center in the reentrant angle was, in his opinion, not a desirable operation. At Mount Sinai Hospital they had classified ulcers of the lesser curvature into groups according to the operation performed, whether a sleeve resection, partial gastrectomy with gastroenterostomy, excision, excision with gastroenterostomy, excision with jejunostomy or jejunostomy. The series of cases included thirty, with eleven deaths, or a mortality of 36 per cent. Of these eleven deaths eight had been caused by postoperative pneumonias. Dr. Berg analyzed this series of cases with reference to the type of operation performed and the results. It had been their experience that excision of an ulcer at the site of reentrant angle, between the vertical and horizontal portions of the stomach, was dangerous. If an ulcer was located at the cardiac end of the stomach excision alone might be indicated. If the ulcer was near the angle the excision should be accompanied by a gastroenterostomy or jejunostomy; the sleeve resection was indicated when the ulcer was within the reentrant angle. The operation of partial gastrectomy and gastroenterostomy was reserved for large indurated and adherent ulcers. He saw no particular advantage in a two-stage operation.

Dr. GEORGE WOOLSEY said that these ulcers of the lesser curvature formed the largest group of gastric ulcers met with surgically. There were a larger number of ulcers of the posterior than of the anterior wall, but the greatest number were located on the lesser curvature. Summing up it might be said that for ulcers not very distant from the pylorus the best operation was resection. If the ulcer left uninvolved a considerable portion of the antrum a mesial resection was indicated, as it sacrificed less of the stomach. Personally the speaker said he did not like the V-shaped incision and he never made such an excision without a gastroenterostomy, for

he had had the experience of having to do a gastroenterostomy afterward, having failed to do it in the first place. According to von Eiselsberg and Payr excision was a bad operation and should be given up. At the same time excision was occasionally indicated in ulcers high up along the cardia, where mesogastric resection was more difficult, but in his opinion all excisions should be accompanied by gastroenterostomy. He did not see any reason for Dr. Berg's experience in the cases with ulcer at the reentrant angle. He had had no such experience. If there was trouble from removal of the nerve centers following an excision at the reentrant angle, why should there not be trouble in a sleeve resection at the same point? A very favorable factor in the sleeve resection was that it paralyzed the sphincter, preventing pylorospasm, so that one did not need to do a gastroenterostomy. These cases of sleeve resection did remarkably well and often did not suffer from postoperative vomiting. He had not had the experience of postoperative vomiting and gradual failure until death without any pathological lesion to explain it, and Dr. Berg's explanation that the trouble was due to the extension of the nerve centers did not appeal to him.

Dr. MEYER M. STARK said that Dr. Berg's clinical deductions were correct and there might be reason to suspect that the deformity resulting from the excision of an ulcer might interfere with the motility of the stomach, but the inference was not correct that there was a considerable nerve supply at the reentrant angle between the horizontal and vertical portions of the stomach. The tonic waves of contraction originated not at this angle but higher up, and proceeded along the border of the lesser curvature from the cardiac portion of the stomach downward to the lower antrum. If owing to the presence of an ulcer the motility of the stomach was interrupted, with a segmental resection and a reunion of the segments the motility that might have been interrupted by the presence of an ulcer is restored. This restoration of motility had been noticed in animals after a sleeve or segmental resection of the stomach. It has been noticed in experimental work on animals that there was a wide undulatory movement which began high up in the stomach and passed downward, and that it was much more active on the lesser than on the greater curvature.

Dr. L. T. LEWALD said Dr. Woolsey had just asked him whether he had made any x-ray observations with reference to the interruption of the peristaltic waves after the different types of operation. After a sleeve resection the stomach emptied very well. His impression was that the waves were not interrupted. The general appearance and tone of the stomach after these resections was good, about similar to that of a normal stomach. As to paralysis of the sphincter the wave was not interrupted there. The speaker expressed himself as convinced that the sleeve resection was the best type of operation for an ulcer located in that region, and he based this opinion on a careful examination of the results of these operations as shown by the x-ray examinations. In the simple excision cases the patients were more apt to have retention and recurrence of hour-glass constriction.

Dr. DOUGLAS asked Dr. LeWald if he had observed whether the peristaltic waves began at the point of resection.

Dr. LEWALD replied that Dr. Barber said the peristaltic waves began high up and were not interrupted at the resected region.

Dr. DOWNES said he thought Dr. Berg was not strictly correct when he said that hour-glass stomach always persisted after resection. He had had five cases. In two, three and one-half years after operation, one could scarcely tell that there had been an operation. In one case he did not excise widely enough—he had placed the clamps too close to the resection. He now made it a practice to open the ends of the clamps and stretch the ends of the stomach before approximating them and when this was done there was very little constriction. He had excised a number of ulcers on the lesser curvature with gastropasty without gastroenterostomy with good results. A number of these cases had been followed from two to five years with roentgenological examinations before and after the operation. The remote results bore out the idea that this was a

very valuable procedure. Dr. Berg has overlooked the question of gastroenterostomy for large pyloric tumors in which group he had five deaths out of 14 cases. In that type of case the two-stage operation, gastroenterostomy followed later by pylorotomy, was a valuable procedure. Both Dr. Crile and Dr. Lilienthal had recommended a two-stage operation in a certain number of their cases. The ulcer disappeared practically the same as in a jejunostomy and the mortality was certainly much lower.

Dr. MILLIKEN said that it was interesting to note the consensus of opinion as to the best mode of operation for ulcers of the lesser curvature. He said that he always did a gastroenterostomy with an excision of the ulcers; even with the excision of a small ulcer at the cardiac end of the stomach.

Dr. JOHN DOUGLAS said that he was sorry that he had been unable to present his case as he had intended. This patient had an ulcer of the lesser curvature which he had excised. Convalescence followed and the patient was improved for several months, although never absolutely well. Two years after the first operation there was a recurrence of symptoms and a second operation. At this operation no deformity was found such as often follows the excision of a hard, indurated ulcer, but there was present a new ulcer of the duodenum. The ulcer was situated very close to the pylorus, and a gastroenterostomy with pyloric exclusion was done. He said that he believed that if an incision or Balfour cautery operation were done, a gastroenterostomy should also be performed, even though the ulcer were located high up on the lesser curvature. In the extensive, hard, indurated, adherent ulcers, especially when the patient is in poor condition, a preliminary gastroenterostomy should be done, and at a second operation a partial resection. This statement would seem to be borne out by Dr. Berg's high mortality in this class of patients. He agreed with Dr. Berg that the sleeve resection was the operation of choice in cases of ulcer of the lesser curvature with hour glass contraction, but in these cases with a small upper pouch, with the ulcer adherent to the liver, this was often almost impossible, or extremely dangerous.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

THE NATIONAL BOARD OF MEDICAL EXAMINERS.

Chicago, October 10-18, 1917.

The examination was conducted orally also, as well as clinically and in the laboratory.

ANATOMY.

1. Describe the elbow joint with overlying structures and muscular attachments in immediate vicinity.
2. Name cavities of heart and describe the valves.
3. Define synarthrosis, amphiarthrosis, diarthrosis. Example of each.
4. Through what arteries is collateral circulation established after ligation of common carotid?
5. Origin, insertion, action, and nerve supply of (a) triceps extensor cubiti; (b) serratus magnus; (c) pectoralis minor; (d) biceps femoris.
6. Describe the lacrimal apparatus.

PHYSIOLOGY.

1. Describe the methods by which may be determined the events of the cardiac cycle in the right and left sides of the heart, respectively, in man. Detail the results.
2. (a) What is the normal stimulus of the respiratory nerve center? (b) What is meant by the "buffer" action of the blood salts and what is its use? (c) What condition supervenes when the "buffer" action is inadequate?
3. (a) What relation has the "pulse pressure" in an artery to the volume of blood passing through it? (b) What are the factors determining pulse pressure?
4. Give evidence as to the functions of the thyroid gland.
5. Describe the origin and function of secretin.

6. Give the various functions of the sympathetic nerve.

7. Describe the stages of protein digestion.

8. Give the qualitative and quantitative essentials for the diet of a working man.

PHYSIOLOGICAL CHEMISTRY.

1. What is an amino acid and how many and what amino acids are found in the protein molecule?

2. Give the characteristic color tests for proteins and the significance from a chemical standpoint of each test.

3. Define a purin body and tell what purin substances are formed in the animal body, what relation they have to one another, and in what form each is eliminated.

4. Give the steps in the formation of urea, uric acid and hippuric acid in the body, and the significance of an excess or a deficiency of each of these substances in the urine.

5. Discuss in detail the coloring matters of the blood and the urine, giving the formation and function of these coloring matters and the significance of their presence in excess in the urine.

ANSWERS.

ANATOMY.

1. The *elbow joint* is a ginglymus or hinge joint, formed above by the lower end of the humerus, and below by the greater sigmoid cavity of the ulna and the head of the radius. The ligaments are (1) the *anterior*, which extends from the front of the humerus just above the coronoid fossa and from the internal condyle to the orbicular ligament and to the under surface of the coronoid process of the ulna; (2) the *posterior*, which extends from the lower end of the humerus and the olecranon fossa to the olecranon process of ulna; (3) the *internal lateral*, which extends from the internal condyle of the humerus to the coronoid and olecranon processes of the ulna; and (4) the *external lateral*, which extends from the external epicondyle to the orbicular ligament and to the external border of the upper end of the ulna. There is a *synovial membrane* which lines the inner aspect of the ligaments, the coronoid and olecranon fossa, and extends into the superior radio-ulnar articulation.

The *overlying structures* are: *In front*, skin, superficial fascia, cutaneous nerves, superficial veins, deep fascia, bicipital fascia, tendon of the biceps, brachialis anticus, brachial artery, median nerve, and recurrent radial and ulnar arteries. *Behind*, the superficial structures, triceps, and anconeus. *Externally*, the extensors and supinators arising from the external condyle of the humerus, the musculospiral and radial nerves and the superior profunda artery. *Internally*, the flexors and pronators arising from the internal condyle, the ulnar nerve, and the inferior profunda artery.

Muscles arising from inner condyle of humerus: Pronator radii teres, flexor carpi radialis, palmaris longus, flexor carpi ulnaris, flexor sublimis digitorum. *Muscles arising from the outer condyle of the humerus:* Extensor carpi radialis brevis, extensor communis digitorum, extensor minimi digiti, extensor carpi ulnaris, anconeus, and supinator brevis. To the *olecranon process of the ulna* are attached the triceps, anconeus, and one head of the flexor carpi ulnaris. To the *coronoid process of the ulna*, the brachialis anticus, pronator radii teres, flexor sublimis digitorum, and flexor profundus digitorum. To the *upper end of the radius*, the biceps, supinator brevis, flexor sublimis digitorum, and flexor longus pollicis.

2. The *cavities of the heart* are the right auricle, left auricle, right ventricle, and left ventricle.

VALVES OF THE HEART. "The *mitral* and *tricuspid* valves are situated in the left and right ventricles respectively at the auriculo-ventricular orifices, and prevent the passage of blood into the auricles during the ventricular systole. They consist of flaps or cusps, two in the mitral, and three in the tricuspid, connected by their bases to the auriculo-ventricular orifices; their free margins and lower surfaces give attachment to the chordæ tendineæ which connect them with the musculi papillares. They are formed of a duplicature of the lining membrane of the heart, strengthened by connective tissue. During the ventricular systole, the pressure

of the blood in the ventricles presses their free edges, or rather their marginal surfaces, together, the musculi papillares regulating the tension of the chords and preventing the valves from becoming retroverted into the auricles.

"The *semilunar valves* guard the aortic and pulmonary openings. They consist of three semicircular folds attached by the convex margin to the wall of the artery at its junction with the ventricle, and are formed by a reduplication of the lining membrane strengthened by fibrous tissue. In the center of each free margin is a little nodule, the corpus Arantii, the three meeting in the center when the valves are closed. On each side of the corpora Arantii is a thin semilunar marginal surface, where the fibrous tissue is absent, called the lunula; these surfaces come in contact when the valves close."—(Ashby's *Notes on Physiology*.)

The *Eustachian valve* is found in the right auricle, between the anterior margin of the postcava and the auriculo-ventricular orifice. It is semilunar in shape and is formed by a duplicature of the lining membrane of the auricle. The *coronary valve* is a semicircular fold of the lining of the membrane of the right auricle; it protects the orifice of the coronary sinus.

3. *Synarthrosis* is an immovable articulation, such as the sutures of the skull. *Amphiarthrosis* is an articulation that permits of limited motion, such as the symphysis pubis. *Diarthrosis* is a freely movable articulation, such as the shoulder joint.

4. *Collateral circulation after ligation of the common carotid*: "(1) Branches of the external carotid on the side tied, anastomosing with the corresponding branches of the opposite side. (2) Anastomoses between the internal carotids of opposite sides through the anterior segment of the circle of Willis—*anterior cerebral* of one side, with the *anterior cerebral* of the other, through the anterior communicating. (3) Anastomoses between the subclavian and the external carotid of the side tied: (a) the deep cervical with *princeps cervicis* of occipital; (b) the vertebral with the occipital; (c) inferior thyroid with superior thyroid. (4) Anastomoses between the subclavian and the internal carotid of the side tied, the vertebral through the basilar and posterior cerebral, with posterior communicating from internal carotid, *i.e.* through the lateral segment of the circle of Willis. (5) Anastomoses of the ophthalmic, from the internal carotid, through the circle of Willis, with branches of the external carotid on the side tied: (a) nasal of ophthalmic with angular of facial; (b) infra-orbital, from internal maxillary, with twigs of facial; (c) supra-orbital and frontal, from ophthalmic, with terminations of the anterior temporal."—(McLachlan and Skirving's *Applied Anatomy*.)

5. **TRICEPS EXTENSOR CUBITI.** *Origin*, immediately below glenoid cavity of scapula, posterior surface of shaft of humerus between insertion of teres minor and upper part of musculospiral groove, external border of humerus and external muscular septum, posterior surface of shaft of humerus below the musculospiral groove, and internal border of humerus. *Insertion*, olecranon process of ulna and deep fascia of forearm. *Action*, extensor of forearm and elbow joint. *Nerve supply*, the musculospiral.

SERRATUS MAGNUS. *Origin*, outer surface and upper border of upper eight ribs and from aponeurosis of the corresponding intercostal muscles. *Insertion*, the ventral aspect of the vertebral border of the scapula. *Action*, it carries the scapula forward and raises its vertebral border; it is concerned in the act of pushing; it raises the acromion process and assists in raising the arm. *Nerve supply*, posterior thoracic.

PECTORALIS MINOR. *Origin*, upper margin and outer surface of third, fourth, and fifth ribs near their cartilages, and from the aponeurosis covering the intercostal muscles. *Insertion*, coracoid process of scapula. *Action*, it depresses the shoulder, draws the scapula downward and inward, and throws the inferior angle of the scapula backward; it aids in forced inspiration. *Nerve supply*, anterior thoracic.

BICEPS FEMORIS. *Origin*, tuberosity of ischium, great sacrospinous ligament, linea aspera of femur. *Insertion*, outer side of head of fibula, and external tuberosity of tibia. *Action*, flexes leg upon thigh and rotates leg slightly outward. *Nerve supply*, great sciatic.

6. The *lacrimal apparatus* consists of the lacrimal

gland and its secretory ducts; the lacrymal canals, which carry the tears to the lacrymal sac, and the nasal duct, which carries them from the sac to the nose.

The *lacrymal gland* occupies a depression in the supero-external angle of the orbit; the anterior margin is connected to the back part of the upper eyelid. The ducts (twelve or fourteen) open by apertures, placed in a row, at the inner surface of the upper lid.

The *lacrymal canals* commence at the *puncta lacrymalia*, which are the openings of the canaliculi, and, arching in the free edge of the lid, pass inward to open into the *lacrymal sac*.

The *lacrymal sac* is placed in a groove formed by the lacrymal bone and the nasal process of the superior maxilla, being behind the *tendo oculi*, and in front of the *tensor tarsi*; it is the dilated upper end of the nasal duct.

The *nasal duct*, formed by the lacrymal, superior maxilla, and inferior turbinal bones, leads from the lacrymal sac to the inferior meatus of the nose, where it opens, the aperture being partly guarded by a valve formed of the mucous membrane. It is about one-half inch long, and is directed downward and slightly outward and backward.—(*Aids to Anatomy*.)

PHYSIOLOGY.

1. "An electrocardiogram obtained by photographing the oscillations of the galvanometer string during the cardiac cycle when different portions of the body surface are connected with the terminals of the string, is shown in the figure, the different features of

which are designated by the letters P, Q, R, S, T. This curve, which represents the relative strength, duration, succession, and direction of the currents during the cycle, it is believed furnished a correct picture of the strength, duration, succession, and direction of the physiologic processes—the excitation and contraction processes—as they arise in the heart muscle during its activity. The interpretations of the electrocardiogram and the significance of its various features are not, in some respects, in as complete accord as seems desirable. In general it may be said that P corresponds to the auricular systole and that Q, R, S, T correspond to the ventricular systole. R and T are always present in physiological conditions at least, while Q and S may, either one or the other or both, be wanting. Einthoven is of the opinion that the general form of the electrocardiogram indicates the path and propagation of the stimulus or the excitation process through the heart, as well as the order of contraction of different portions of the ventricular walls, both of which are in harmony with the origin, course, and ultimate distribution of the auriculoventricular conduction system as determined by Tawara. The record presents first a horizontal portion—the image of the galvanometer string—which indicates that the string is at rest by reason of the fact that all portions of the heart during the diastolic pause are isoelectric or of equal electropotential. P is the result of the contraction of the auricle, indicating a condition of negativity toward the ventricle, which is now electropositive, in consequence of which the electric currents pass down the heart, thence to the body surface, thence through the galvanometer circuit and back to the heart, causing the string as they pass through it to move outward. With the cessation of the auricular contraction the string returns to its position of rest. The more or less horizontal line between P and Q indicates that both auricles and ventricles are now at rest and in

the same state of electric potential. The passage of the excitation process through the conduction system, which is now taking place, from its beginning to its terminations is, in and of itself, too feeble to cause a deviation of the thread under the conditions of tension necessary for the registration of the other features of the electrocardiogram. The system of points or waves, negative and positive, Q, R, S, in the first part of the ventricular portion of the electrocardiogram permits of the inference that the stimulus arrives and the contraction arises at once or almost at once in different places of the ventricular masses. The first point Q indicates that the stimulus arrives first at a point lying near to the apex and calls forth a contraction of moderate degree, establishing a certain degree of electronegativity toward the base which is now electropositive. The direction of the point below the horizontal portion is due to the direction of current through the heart and galvanometer, which is of course the reverse of the current that originates in the auricle and which gives rise to P. The point R, which immediately follows, indicates that the stimulus has arrived at the base of the ventricle, calling forth a more pronounced contraction and a greater degree of electronegativity than that present at the apex. The point S indicates that soon thereafter the stimulus reaches regions lying nearer to the apex of the ventricle, calling forth a contraction and establishing an electronegativity which soon gains the upper hand. The horizontal portion of the electrocardiogram between the system of points Q, R, S on the one side and the point T on the other side represents a contraction state in which the entire muscle mass of the two ventricles participates in the same measure, and hence all portions are in a condition of equal negativity, for which reason the string remains stationary. It is during this period that the ventricles are engaged in driving the blood out of their cavities into the aorta and pulmonic artery. T, the last peak of the ventricular portion of the electrocardiogram, is directed upward, and hence reveals the fact that the base of the ventricle is at this moment in a condition of greater electronegativity than are portions of the heart lying nearer the apex. The origin of the T peak has been a subject of much discussion, but the investigations of Gotch have made it apparent that it is due to the contraction of muscle fibers which have not before been brought into action; that is, fibers near the root of the aorta, in that portion of the ventricle which is the homologue of the bulbus arteriosus in the lower animals. The contraction of this region completes the discharge of the blood from the ventricular cavity. The activities of the different parts of the heart indicate by the lettering may be summarized as follows (Ott):

PHASE OF ELECTROCARDIOGRAM	APPROXIMATELY
A. Activity of auricle	presystole. Period of filling of the heart (ventricle).
h. Activity of His's bundle	
J. Activity of papillary system	Period of distention of the heart.
—intersystole	
t. Activity of middle layer of ventricular muscle	systole. Period of ventricular discharge.
F. Activity of conus arteriosus	
P. Rest of the whole heart—	Period of filling of the heart.
pause of heart	

—(Brubaker's *Physiology*.)

2. (a) The normal stimulus of the respiratory center is, probably, an excess of carbon dioxide in the blood. Other views are: (1) that it is due to a lack of sufficient oxygen in the blood, and (2) that it is due to both a lack of sufficient oxygen and an excess of carbon dioxide in the blood.

(b) "Carbonic acid is continuously being thrust into the blood by the tissues, but nominally it produces no great preponderance of H ions, and the reaction is but little disturbed; this is because the blood plasma contains certain substances, spoken of as 'buffers,' which enter into loose combination with the CO₂, and so prevent it raising the acidity of the blood fluid. These substances are sodium bicarbonate, sodium phosphate, and proteins. The sodium bicarbonate secures the prepon-

derance of the CO_2 ; the sodium phosphate helps by increasing the amount of sodium bicarbonate according to the following equation: $\text{Na}_2\text{HPO}_4 + \text{CO}_2 + \text{H}_2\text{O} = \text{NaH}_2\text{PO}_4 + \text{NaHCO}_3$; and about one-third of the CO_2 is in loose combination with the proteins; finally about 5 per cent. is present in simple solution."—(Halliburton's *Physiology*.)

(e) When the buffer action is inadequate acidosis supervenes.

3. (a) "The pulse pressure is, with qualifications, an indication of the cardiac output per beat. As a rule, increased ventricular output leads to increased pulse pressure and *vice versa*. The attempt has been made to establish formulas enabling one from the pulse pressure and the cardiac rate to estimate alterations in the cardiac output per minute; in other words, of the blood flow from the heart. As a rule changes in pulse pressure and aortic volume flow are in the same direction, but this is not always true, for aortic regurgitation and so common a condition as arteriosclerosis tend to produce alterations of these factors in contrary directions. Moreover only under very limited conditions is there any constant quantitative relation between the respective changes in these factors. Hence all attempts aiming to express in figures the blood flow on the basis of the pulse pressure should be regarded with suspicion."—(Norris's *Blood-Pressure*.)

(b) The factors which determine pulse-pressure are: The rate of the heart beat, the peripheral resistance, and the systolic discharge. Pulse pressure is increased by: Decreased peripheral resistance, decreased heart rate, and increased systolic discharge. Pulse pressure is decreased by: Increased peripheral resistance, increased heart rate, and decreased systolic discharge.

4. "The thyroids are essential to life. If they are wholly removed death occurs with cachectic symptoms. If part of the gland is left *in situ* or transplanted into another part of the body, or if accessory thyroids capable of hypertrophy are left behind, or if thyroid substance or its active principle be ingested, the consequences of removal will be less severe, or may be escaped entirely. Such regeneration, or compensation, for probably both are concerned, is more likely to occur in young animals, and the resulting changes will depend partly upon the youth of the subject. Two opposite sets of symptoms follow from diminished and excessive thyroid activity respectively. With diminution, growth is lessened. In the young animal not only is macroscopic growth diminished but cells fail to reach their proper development and the connective tissue remains myxomatous. The skin and hair show impaired growth. The nervous system undergoes degeneration and its function is impaired, as shown by psychic, motor, and sensory disturbances. The heat regulation, metabolism, and gaseous interchange are all depressed. The results of lessened activity of thyroid function are seen in myxedema and cretinism. Excessive activity of thyroid function, produced experimentally by feeding with suitable preparations, is shown by excessive metabolism, decrease of weight, not only from destruction of fat but also of proteins, increased growth of long bones in young animals, and various nervous symptoms affecting the heart (palpitation and tachycardia), the central nervous system (irritability, sleeplessness), and the peripheral nerves and muscles. Glycosuria is not rare. These conditions will be found in connection with Graves' disease. The present conception of thyroid function is that the action is chiefly exerted through a secretion, thyroglobulin, which acts as a hormone. The hormone may be compound, with special affinities and activities. At present we can recognize only effects on many organs and tissues, some stimulating, some inhibiting, but we do not know whether the hormone action is different or exerted through the nervous system."—(Osler and McCrae's *Modern Medicine*.)

5. *Secretin* is a hormone which is formed in the mucous membrane of the small intestine. It is formed by the action of the acid chyme from the stomach acting on *prosecretin*. The function of secretin is to promote the flow of the pancreatic juice; it is believed also to assist in the production of the succus entericus, and to stimulate the flow of bile.

6. The functions of the sympathetic nervous system: "It may safely be said that the sympathetic system has, to a great extent, a controlling influence over the secre-

tion of most of the glands, the lacrymal, the salivary, the sweat glands, the glands of the stomach and intestines, the liver, the kidney, etc.; that it presides over the circulation by regulating the caliber of the blood vessels and the action of the heart; that it influences respiration; and, finally, that all involuntary muscles, those of the digestive apparatus, of the genitourinary system, of the hair follicles (pilomotor nerves), are under its control to such an extent that, for instance, in certain mammals the bladder still continues to fulfill its function for weeks after all the cerebrospinal motor nerves leading to it have been severed. In short, we find that all vegetative life of the organism is, to a greater or lesser extent, under the control of the sympathetic system. Therefore it may properly be called the vegetative nerve system *par excellence*."—(*Reference Handbook of the Medical Sciences*.)

7. The digestion of protein takes place in the stomach and in the small intestine. In the stomach it is acted upon by the pepsin in the presence of hydrochloric acid, and is changed into simpler substances. First, it is converted into a soluble globulin, then acid metaprotein is formed, then two primary proteoses (protoproteose and heteroproteose) are produced, deuteroproteose or secondary proteose is then formed, and then the final stage of protein digestion in the stomach is reached by the formation of peptone which is probably a mixture of polypeptides. Sometimes, if sufficient time is allowed, aminoacids may be produced. In the small intestine the passage of the acid chyme from the stomach starts the action of the secretin and promotes the flow of the pancreatic juices; the trypsin (in an alkaline medium) splits up the protein into soluble globulin, and then into alkaline metaprotein; this is split up into proteoses, notably deuteroproteose, then into peptone and polypeptides; these last are finally split up into aminoacids, hexone bases, and tryptophane.

8. Assuming that a working man requires a diet which produces say from 3,000 to 3,300 calories a day, and that we accept Rubner's figures that 1 gram of protein has a calorie value of 4.1, 1 gram of fat 9.3, and 1 gram of carbohydrate 4.1, then the following table (taken from Stewart's *Physiology*) will show the required diet. We may take 500 grams of bread and 250 grams of lean meat as a fair quantity for a man fit for hard work. Adding 500 grams milk, 75 grams oatmeal (as porridge), 30 grams butter, 30 grams fat (with the meat, or in other ways), and 450 grams potatoes, we get approximately 20 grams nitrogen and 300 grams carbon contained in 135 grams protein, rather less than 100 grams fat, and somewhat over 400 grams carbohydrates. Thus:

	Proteins.	Fat.	Carbo- hydrates.
(9 oz.) 250 gm. lean meat.....	55	8.5	..
(18 oz.) 500 gm. bread.....	40	7.5	245
(¾ pt.) 500 gm. milk.....	20	20	25
(1 oz.) 30 gm. butter.....	..	27	..
(1 oz.) 30 gm. fat.....	..	30	..
(16 oz.) 450 gm. potatoes.....	10	..	95
(3 oz.) 75 gm. oatmeal.....	10	4	48
	135	97	413

This would be a fair "hard work" diet for a well-nourished laborer.

135 gm. protein	× 4.1 =	553.5
97 gm. fat	× 9.3 =	902.1
413 gm. carbohydrate	× 4.1 =	1693.3

Total calories = 3148.9

PHYSIOLOGICAL CHEMISTRY.

1. An aminoacid is an organic acid in which one or more of the hydrogen atoms in the chain (not in the COOH group) have been replaced by the amino group, NH_2 . Up to the present, eighteen aminoacids have been found in the protein molecule. (1) Glycine, glycoll, or aminoacetic acid; (2) alanine, or aminopropionic acid; (3) valine, or aminoisovaleric acid; (4) leucine, or aminoisocaproic acid; (5) isoleucine, or aminomethylethylpropionic acid; (6) phenylalanine, or phenylaminopropionic acid; (7) tyrosine, or oxyphenylaminopropionic acid; (8) serine, or hydroxyaminopropionic acid; (9) cystine, or thioaminopropionic acid; (10) aspartic acid, or aminosuccinic acid; (11) glutamic acid,

or aminoglutaric acid; (12) proline, or pyrrolidine carboxylic acid; (13) oxyproline; (14) arginine, or guanidineaminovaleric acid; (15) lysine, or diaminocaproic acid; (16) ornithine, or diaminovaleric acid; (17) histidine, or imidazoleaminopropionic acid; and (18) tryptophane, or indolaminopropionic acid.

2. CHARACTERISTIC COLOR TESTS FOR PROTEINS: (1) The *biuret reaction*. The protein solution is made strongly alkaline with caustic soda or potash and a few drops of a dilute solution of copper sulphate are added carefully so as to avoid an excess. A purple color is obtained. Some proteins (peptones) give a red purple, others a blue purple. If only a blue color, without any mixture of red, is obtained, no protein is present. At present this reaction gives the best single test for protein. It obtains its name from the fact that it is given by biuret $\text{HN} < \begin{smallmatrix} \text{CONH}_2 \\ \text{CONH}_2 \end{smallmatrix}$, a compound that may be formed

by heating urea. Two molecules of urea give off a molecule of ammonia and form biuret. (3) The *Millon reaction*. The protein solution is boiled with Millon's reagent. The solution or the precipitate, if one is formed, takes on a reddish color, which varies in intensity with different proteins. Millon's reagent consists of a solution of mercuric nitrate in nitric acid containing some mercurous nitrate. This reaction is supposed to be given by the tyrosine (oxy-aromatic) grouping in the protein molecule, and fails, therefore, with those proteins in which tyrosine is not present. (3) The *xanthoproteic reaction*. Nitric acid is added to strong acid reaction and the solution is then boiled. After cooling, ammonia is added. The ammonia causes the development of a deep-yellow color if protein is present. This reaction is supposed to be due to the presence in the molecule of the groupings belonging to the aromatic series. (4) *Adamkiewicz's reaction*. A mixture is made of one volume of concentrated sulphuric and two volumes of glacial acetic acid; if the protein solution is added to this mixture and warmed a reddish-violet color is obtained. According to Hopkins and Cole, the reaction depends upon the presence of glyoxylic acid in the acetic acid, but according to Homer it is really a formaldehyde reaction. The action of the sulphuric acid upon the glyoxylic acid produces some formaldehyde. This reaction seems to be due to the tryptophan grouping in the protein molecule. (5) *Liebermann's reaction*. Dry protein purified with alcohol and ether gives a blue color upon boiling with strong hydrochloric acid. (6) The *lead sulphide reaction*. The protein solution is boiled with a solution of a lead salt made strongly alkaline with soda or potash. A black precipitate or black or brown coloration results, according to the amount of protein. The color is due to the splitting off of sulphur and formation of lead sulphide. It is given, therefore, by the sulphur-containing groups in the protein molecule. (7) The *Molisch reaction*. A few drops of an alcoholic solution of α -naphthol are added to the protein solution and then strong sulphuric acid. A violet color is obtained. This reaction is given by the carbohydrate grouping in the protein molecule. The strong acid forms furfural from this group, which then reacts with the naphthol. The reaction is not given by those proteins that do not contain a carbohydrate group.—(Howell's *Physiology*.)

3. The *purine bodies* are a group of substances so called because of their close relationship to purine, the mother substance of the group. Their base of formation is the so-called purine ring, which consists of two urea radicals linked together by a central chain of carbon atoms. They are decomposition products of nuclein. The purine substances formed in the body, and their relation to each other, are shown in the following table:

Purine		$\text{C}_5\text{H}_4\text{N}_4$	
Hypoxanthine	..	$\text{C}_5\text{H}_4\text{N}_4\text{O}$	 Monoxypurine
Xanthine		$\text{C}_5\text{H}_4\text{N}_4\text{O}_2$	 Dioxypurine
Uric acid		$\text{C}_5\text{H}_4\text{N}_4\text{O}_3$	 Trioxypurine
Adenine		$\text{C}_5\text{H}_5\text{N}_5$	 Amino-purine
Guanine		$\text{C}_5\text{H}_5\text{N}_5\text{O}$	 Amino-oxypurine

Purine itself is not found in the body. Xanthine is found in the pancreas, spleen, liver, thymus, kidneys and brain; it is eliminated in the urine. Hypoxanthine is found in the same places as xanthine, and is also

eliminated in the urine. Guanine is found in the spleen, liver, pancreas and urine and sometimes in the blood; it is eliminated in the urine. Adenine is found in the thymus, and sometimes in the blood and urine. Uric acid is found in the urine, and is eliminated in the urine.

4. *Urea formation*. The greater part of the urea produced in the body is formed in the liver. The liver cells form the urea from two sources: (1) The larger amount, produced by the liver cells, is derived from the amino-acids which have been absorbed from the small intestine, and which are not required by the tissues; this constitutes the *exogenous urea*. (2) The smaller amount, produced by the liver cells, is derived from the ammonium carbonate, which is the outcome of nitrogenous catabolism, and which is derived from the tissues; some is also produced by the action of the uricolytic enzyme upon uric acid; this constitutes the *endogenous urea*.

Uric acid formation. Uric acid is formed in the liver more abundantly than in other tissues. It is the result of the complete oxidation of certain purine bases, which are derived partly from the nucleo-protein in the tissue (*endogenous uric acid*), and partly from the nucleo-protein of the food (*exogenous uric acid*). Much of the uric acid thus formed is further changed by the uricolytic or uricolytic enzyme, produced by the liver cells, into urea.

Formation of hippuric acid. Hippuric acid is formed by the cells lining the urinary tubules. Here, probably as the result of enzyme action, the benzoic acid of the food is synthesized with glycine produced from protein, or by the renal cells themselves, to form hippuric acid. The benzoic acid is derived almost entirely from the food; the glycine may be derived by the process of either exogenous or endogenous protein metabolism. It is easy to understand, then, that the occurrence of hippuric acid in the urine stands in the most intimate relation to the presence and quantity of benzoic acid in the food. A man fed upon a "benzoic acid free" diet will excrete no hippuric acid; if given a diet containing large amounts of benzoic acid (*i. e.* if fed largely upon fruits) he will eliminate a much larger quantity of this acid.—(From Lyle's *Physiology*.)

The amount of *urea* eliminated in the urine depends largely upon the amount of nitrogen contained in the food, and also upon the extent of protein metabolism going on in the body. It is increased in fevers, in diabetes, pneumonia (during resolution); it is decreased in diseases of the liver. The amount of *uric acid* eliminated in the urine depends largely on the amount of purines in the food, and also on the amount of nitrogen in the food. It is increased in leukemia and in diseases of the liver, gout and rheumatism.

5. The *coloring matter of the blood* is hemoglobin; this is a protein which consists of globin and hematin; it contains iron, and is the oxygen-carrier of the blood. Among its derivatives are the bile-pigments, biliverdin and bilirubin; the urinary pigments, such as urobilin, and some abnormal derivatives found in certain pathological conditions. The *coloring matter of the urine* is due to urochrome (whose origin is not settled), urobilin, uroerythrin, and hematoporphyrin. Urobilin is formed in the digestive tract from bilirubin; it occurs in the urine in excess when there is an excess of bile pigment due to excessive breaking down of the red blood corpuscles, as in pernicious anemia, also in fevers. Uroerythrin is found with the urates in a urinary sediment. Hematoporphyrin occurs in excess in cases of sulphonal (and other drug) poisoning. Indoxyl is also found in the urine; it is formed in the intestines as a putrid decomposition product. Hemoglobin is found in the urine when there is an active hemacytolysis going on in the body, as in case of severe burns. Bilirubin is found in the urine when icterus is present.

(To be continued.)

Diabetes Insipidus and Pituitrin Therapy.—Kraemer treated a fireman aged 26, who suffered from polyuria, failing libido and cracking of the voice, with pituitrin. The polyuria was promptly reduced from 10 to 5 liters daily. The patient slept much better.—*Münchener medizinische Wochenschrift*.

MALNUTRITION AMONG SCHOOL CHILDREN. A STUDY

BY THE PUBLIC HEALTH COMMITTEE OF THE NEW
YORK ACADEMY OF MEDICINE.*

1. *Statement of the Problem.*—The proper physiological, mental, and moral development of children is one of the most vital concerns of the nation. Stunted physical growth retards the normal unfolding of facultative functions and is a danger signal to the body politic.

Malnutrition is one of the most potent factors hindering the normal course of a child's development. Although distinctly a pathological entity, malnutrition is not a disease but a morbid physical condition. It may be symptomatic of definite systemic disease such as tuberculosis, cardiovascular or digestive disturbances or it may be the only evidence or result of defective metabolism or of complex and divers physiological and environmental conditions.

Insanitary surroundings, improper habits of life, lack of sleep and unsuitable food, all oftentimes due solely to ignorance, may be responsible for just as much malnutrition as is caused by poverty and disease.

Whatever its causes, malnutrition is a social menace as it hampers the natural development of the functions of mind and body and predisposes its victims to permanent life handicap.

Insofar as malnutrition is due to environmental causes it invariably lends itself to successful treatment. Every effort should be made to combat it among children. The prevention of malnutrition is a distinct public health function.

2. *Statistics of Malnutrition.*—Various studies have been made in an endeavor to gauge the prevalence of malnutrition. Some were based on the relation of weight and height of the children with-

out reference to age; others took the age factor into consideration; and still other estimates are based on purely symptomatic evidence without relation to weight. The various studies made in this country and in England indicate that on the average at least 10 per cent. of our boys and girls in the elementary and grammar schools show the well recognized symptoms of malnutrition.

The following table,¹ embodying the results of physical examinations of 2,169 children of England, outside of the City of London, shows that 16.3 per cent. of the children examined were found to be subnormal with regard to the state of their nutrition. The high percentage of malnutrition is the more striking since the larger proportion of the children examined came from rural districts where the standard of nutrition among children is, on the average, higher than in cities.

TABLE 1.

Local Education Authority	Excellent	Normal	Below Normal	Very Bad
Counties.....	6,745—11.7%	45,176—78.7%	5,268—9.2%	237—0.4%
County boroughs....	12,168—10.8%	78,475—69.4%	20,083—17.8%	224—2.0%
Boroughs.....	2,311—14.0%	11,817—71.5%	2,211—13.4%	187—1.1%
Urban districts.....	2,163—14.7%	10,036—68.1%	2,272—15.4%	262—1.8%
	23,387—11.6%	145,504—72.1%	29,834—14.8%	2970—1.5%

The problem of malnutrition among school children has received very serious consideration on the part of the school medical authorities of England. Since 1907 the school medical inspection in England has been carried on in a systematic way. The procedure as well as the reports is uniform, in this way facilitating comparative studies. A summary of the physical examinations is given annually in the report of the Medical Officer of the Board of Education.

Many cities in Great Britain also have made intensive studies of the problem of malnutrition in its various bearings. Dunfermline, Scotland, was the pioneer in the movement and the practice of recording the nutritional condition of each child upon examination has been followed throughout England. The classification adopted is rather arbitrary and lacks precision. It segregates the children into four groups as given in the headings of the above table and designates their nutritional state as: 1. Excellent, 2. Normal, 3. Below Normal, and 4. Very Bad. The application of this scale, imperfect though it be, has helped to bring out certain important aspects of the problem and to center the attention of the medical inspectors on the nutrition of the school children.

In his comprehensive analytical study of the "Health and Physique of School Children," which

*The report was prepared by E. H. Lewinski-Corwin, Ph.D., and approved by the Public Health Committee. The membership is as follows: Charles Loomis Dana, M.D., Chairman; James Alexander Miller, M.D., Secretary; John S. Billings, M.D., Nathan E. Brill, M.D., Robert J. Carlisle, M.D., Floyd M. Crandall, M.D., Lewis Fox Frissell, M.D., Arpad G. Gerster, M.D., S. S. Goldwater, M.D., John A. Hartwell, M.D., Thomas W. Hastings, M.D., L. Emmett Holt, M.D., Abraham Jacobi, M.D., Howard Lilienthal, M.D., Walter L. Niles, M.D., Bernard Sachs, M.D., Thomas W. Salmon, M.D., Frederic E. Sondern, M.D., W. Gilman Thompson, M.D., Frederick Tilney, M.D., Philip Van Ingen, M.D., Karl M. Vogel, M.D., George B. Wallace, M.D., Herbert B. Wilcox, M.D., E. H. Lewinski-Corwin, Ph.D., Executive Secretary.

comprises 800,000 English children, Arthur Greenwood, of the School of Economics of the University of London, points out that the estimated 10 per cent. of the school children of England suffering from malnutrition is undoubtedly a very conservative figure. From one-sixth to one-fifth of the children would probably be found to be suffering from some degree of malnutrition if a uniform standard of gauging the condition were established. "Where the percentage of ill-nourished scholars is very low, it seems that the standard of nutrition adopted has been somewhat low, and that, taking the country as a whole, not merely 10 per cent., but probably a number approaching 20 per cent. show perceptible signs of malnutrition."

3. *Conditions in New York City.*—The condition of malnutrition among the school children of New York City is not different from that prevailing in England as far as the available data indicate. The following table shows that the proportion of children discovered to be suffering from malnutrition has increased as the attention given to that condition by the medical inspectors has become more pronounced.

Beginning in December, 1915, the Dunfermline classification was applied to New York City and the nutritional condition of each child was recorded upon physical examination. Immediately the percentage of cases falling into groups 3 and 4 of the Dunfermline scale increased almost threefold. About 16 per cent. of the children were found to need either supervision or medical treatment. For the first nine months of the present year the per cent. of malnourished was put down as 10. On the basis of this lower figure there are, in New York City, over 100,000 elementary school children in need of attention on the score of under-nourishment.

TABLE II.—MALNUTRITION AMONG NEW YORK CITY SCHOOL CHILDREN.

Year	Number Found to be Suffering From Malnutrition.	Number of Physical Examinations Made During Year.	Per Cent. of Malnourished.
1909.	7,249	231,081	3.1
1910.	5,691	266,426	3.3
1911.	5,845	230,243	2.5
1912.	8,363	287,469	2.9
1913.	13,991	330,179	4.2
1914.	16,181	308,595	5.2
1915.	17,800	278,174	6.4
1916, Queens excluded	31,791	203,366	15.6
1917, first nine months	21,269	224,963	9.9

Both the Health Department and the Association for Improving the Condition of the Poor of New York City consider 10 per cent. an underestimated and very conservative figure by which to be guided. Here, as in England, it is a common practice among school physicians to consider malnutrition as a relative condition. That is to say, in examining children of a certain school the physicians consciously or unconsciously take the average of the school as a standard and accordingly divide the children into four groups. In the schools located in the poorer districts of the city it may happen that virtually all the children suffer from some degree of malnutrition. Yet grades 1 and 2 show relatively the same percentage as in the schools in the better sections of the city where the majority of the children are fairly robust and well nourished.

The diagnosis of malnutrition in the New York

public schools is made entirely without reference to the relation of weight to age of the children. The rules of the Bureau of Child Hygiene specify that in recording health conditions of school children weight should be taken into account, but with few exceptions our public schools are not equipped with scales. The only schools supplied with scales are those which maintain fresh air classes. The scales are invariably located in the open air classrooms and are not readily accessible. Moreover, they have not been adjusted for many years and are not used in conjunction with the routine physical examinations. All malnutrition records, therefore, must of necessity be based exclusively on the well recognizable clinical symptoms. In this connection it may be of interest to quote from a recent article by Mr. Frank A. Manny of the Association for Improving the Condition of the Poor, relating to a series of examinations of the same group of children made independently by three physicians. He says that although "ordinarily nutrition is one of the least agreed upon of defects, the results showed greater agreement than in the case of bad teeth even, and much greater unanimity than was given to tonsil and nasal breathing defects." As was to have been expected, the agreement was more pronounced in the cases of defective nutrition than in the superior nutrition group.

It is a pity that the lack of equipment prevents the school medical inspectors from registering the weight and height of the school children. These measurements, when properly and scientifically correlated with age, nutritional and other conditions, would supply us with a vast amount of instructive and valuable knowledge. The existing tables of the relation of weight and height to age are either obsolete, as is the Bowditch scale, or based on measurements of children of certain social groups, such as Baldwin's study of pupils in private schools. The Boas scale is, for the time being, the most serviceable as it is a combination of several scales. It is based on a larger number of measurements than any other scale and is more adapted to a cosmopolitan community like New York City, for it takes account of various racial stocks.

4. *Causes of Malnutrition.*—The causes of the large prevalence of malnutrition among school children can be divided into two groups: external and intrinsic. In the first group would come unpropitious environment, poverty, ignorance and bad domestic management; in the second would fall digestive, respiratory and circulatory disablenents and also those arising from bad heredity.

A. *Environmental Causes.*—The unhygienic mode of living in many of the families among the uneducated classes, together with an utter ignorance of proper dietetics, are in a large measure responsible for the devitalization of the children. In many homes the children are given tea, coffee and beer and the general diet is not properly balanced. They eat at irregular hours and do not masticate the food properly. They do not have proper supervision, getting to bed late and sleeping in ill-ventilated rooms. In the 1916 Report the General Medical Officer of the Board of Education of England draws attention to "the ill effect of too little sleep on the nutrition of the child," and states that some school doctors consider that "the Daylight Saving Act has

operated injuriously in this respect by reducing the sleep of children in some places by approximately one hour."

Usually, but by no means always, these conditions are associated with poverty which is thus alone held responsible for the phenomenon of malnutrition, while in reality malnutrition has many more than this one origin. It is undoubtedly true, however, as the various careful studies of workingmen's budgets and standards of living show, that the average earnings in the large majority of these families are insufficient to insure a proper standard of life. Robert Coit Chapin's study of 287 typical New York workingmen's families with from two to four children under sixteen years of age, the earning capacity of which varied from \$600 to \$1,000 per annum, showed that 24 per cent. of these families were underfed, 53 per cent. were overcrowded and 15 per cent. were both underfed and overcrowded. A recent and comprehensive study by Streighthoff showed that only 30 per cent. of the male workers over sixteen years of age, employed in manufacturing, mining, trade and transportation, were earning between \$626 and \$1,044, while 60 per cent. fell below it and 10 per cent. rose above it. Assuming that the nutritional conditions in families with an income of less than \$626 are not worse than those found in the Chapin group earning from \$600 to \$1,000, the number of children who, because of economic conditions, fall below the normal nutrition standard must be very considerable. Wages have risen since the data for the above studies were gathered, but the rate of increase of the cost of food and other necessities has measurably outrun the rise of the wage schedule. However plausible the connection between low economic status and undernourishment may be, scientifically established proof is lacking of the casual relation between the two.

TABLE III.

	Number of Children.	Per Cent.

Defective heredity	6	4.6
Pampering	4	3.0
Excessive growth	1	0.8
	131	100.0

Several years ago at the International Congress on School Hygiene, Dr. I. O. Woodruff presented the results of a careful study of the problem in connection with the children in the fresh air classes of New York City, which was undertaken in co-operation with the Committee on the Prevention of Tuberculosis of the Charity Organization Society. "The study of the home conditions," to quote the report, "has failed to show that either poor economic or hygienic conditions are a potent factor in determining either the degree of malnutrition and anemia or the progress of the child in the fresh air class." The conclusion of the study was that until more scientific evidence has been established malnutrition will have to be considered "as due either to individual susceptibility or to some other factor not yet determined." Families having the same income and the same number of children vary greatly in their nutritional state. Ignorance and

bad domestic management, which frequently prevail among those having low incomes, as well as bad habits of living, have indubitably a great deal to do with the existing nutritional debilities.

Dr. Badger of Wolverhampton, England, classified the factors that caused malnutrition in 131 cases, with the following results*:

On the other hand, within the last few years England has shown an appreciable improvement in the degree of nutrition of the children, as indicated in the diminished need of school feeding, which is accounted for by the improvement in the economic status of the wage-earning population. The following table shows the decline in the extent of school feeding:

TABLE IV. STATISTICS OF MEALS SERVED TO SCHOOL CHILDREN IN ENGLAND AND WALES.

School Year.	Total Number of Children Fed During Year.	Total Number of Meals Provided During Year	Cost per Meal in Pence.
1912-1913	358,306*	19,001,729	2 32
1913-1914	156,531	11,525,593	2 43
1914-1915	422,401	29,560,316	2 47
1915-1916	117,901	9,930,074	4 10
1916-1917	63,939	5,781,589	5 48

*This large number was partly accounted for by the coal strike of 1912.
†This increase is due to the needs which arose at the outbreak of the war.

The Chief Medical Officer of the Board of Education of England and Wales attributes this decline to the fact that "there was a great increase in wages associated with the rapid increase in employment. In due time this pronounced social change reflected itself in the homes of the people and in the feeding and clothing of the children. The evidence from school doctors and the Board's medical inspectors in all parts of the country is to the effect that in 1916 the children were, on the whole, better fed and better clothed than at any time since medical inspection was introduced." This would argue that poverty has a very distinct and direct bearing upon the malnutrition of children. The good showing for the last two years in England is still more striking when one considers that there has been a shortage of foodstuffs in the country, and also that a very large number of mothers have been engaged in industrial and other pursuits. Jointly with the possibilities of education in hygiene, it holds out great hopes for future successful results in combatting the evils of malnutrition among school children.

Housing.—Housing is another physical element which is frequently spoken of as having a bearing on the growth of children. It is exceedingly difficult to establish a direct correlation between housing and malnutrition, as the housing influence cannot easily be separated from the other conditions which accompany it. Congestion is usually associated with a number of other unpropitious circumstances. Similarly, spaciousness of home usually means higher economic and other standards. The factor of housing cannot be dissociated from the accompanying conditions and it is therefore impossible to gauge its single influence accurately.

Dr. William Leslie Mackenzie and Captain A. Foster, in their study of the physical condition of 72,857 children attending the public schools of Glasgow, Scotland, made a number of interesting observations regarding the effect of housing on the physique of the children, which throws a light on

the possible relationship. They found, for instance, that the average weight and height of children between the ages of five and eighteen years varied with the spaciousness of the home, as can be seen from the following table:

Number of Rooms in House.	Boys.		Girls.	
	Weight, Lbs.	Height, In.	Weight, Lbs.	Height, In.
1 room	52.6	46.6	51.5	46.3
2 rooms	56.1	48.1	54.8	47.8
3 rooms	60.6	50.0	59.4	49.6
4 rooms	64.3	51.3	65.5	57.6

B. Intrinsic Causes.—The second group of causes—intrinsic—are either entirely unrelated to or only partially dependent upon the external causes. Some of the debilitating factors, such as chronic absorption from diseased tonsils, decayed teeth or obstructed nasal breathing, can easily be remedied, as can also some respiratory or digestive disturbances.

There is however another group of factors arising from some obscure disease or physical defect which cannot readily be alleviated. Then, too, the influence of heredity must be considered in making provisions and plans for meeting the malnutrition problem in a medical way.

5. Agencies Dealing with the Problem of Malnutrition.—**A. Clinics for Malnourished Children.**—The group of children who suffer from malnutrition as a result of bad habits of living or a deficiency of proper food is of considerable size. The children in this group present all the symptoms of malnutrition and yet suffer from no definite clinically recognized disease. With them diet is the main thing at fault. Several of the clinics in New York have recognized this fact and endeavored to deal with these children in the way best fitted to meet their condition, namely, through the education of the parents or guardians as to their needs. The results of the educational efforts have been very encouraging.*

In the Bellevue Clinic, Dr. Charles Hendee Smith has been able to report that 66.5 per cent. of the children have gained two and a half times the expected weight rate for their ages during the first six months of treatment. The children are given repeated physical examinations at certain intervals, and carefully prepared charts are kept to indicate their progress under certain prescribed conditions of diet and routine of living. In order to follow up the cases in their homes to see that the rules are observed, a social worker is attached to the clinic. Upon the interest of the physicians and the frequency of home visits and the tact of the social worker depend the success of the treatment. The children are assembled in groups at the clinic and are stimulated to an active interest in the charts marking the progress or retrogression in their weight. A healthy concern in their own welfare has been awakened, and no tendency toward introspection has been observed among the children.

The group method of handling these cases seems

*The five malnutrition clinics in the City of New York are in connection with Bellevue Hospital, Post-Graduate Hospital, Cornell University Clinic, the Bowling Green Neighborhood Association, and the Brooklyn Association for Improving the Condition of the Poor.

to be the most successful and economical, and by a more general extension of it in the dispensaries of the city beneficial results can be obtained in a very large number of cases. By exhibits and spoken word the parents are instructed in the proper care of children and in their dietary needs and the response is gratifying in the majority of instances. This suggests the desirability of having parents present at the schools when the school medical inspectors make the physical examinations of the children. The educational value of the physicians' instructions cannot be overestimated and the success of such a procedure has been fully demonstrated in England in connection with medical school inspection. In England, where from 70 to 80 per cent. of the parents attend the physical examinations, this practice has been one of the most effective means of health education and has brought the desired results in many instances. A similar practice of insisting upon the parent's presence during the examination by the school doctor would be very desirable in our school medical system.

The successful experiment in group treatment of malnutrites in special classes might to advantage be more generally extended and should be carried on in conjunction with the pediatric departments, although the attention of other departments of the dispensaries might also profitably be directed toward these efforts.

In addition to the five special nutrition clinics, there are other agencies in the field, which have been dealing with this problem for sometime in other ways. Conspicuous among these activities are the special fresh-air classes for sub-normal children, and school lunches.

B. Fresh-Air Classes.—The fresh-air classes have been going through the experimental stage for a number of years and received special impetus in 1915. While there were 726 children receiving instruction in these classes in 1914-1915, the number increased to 1830 in the following year, 1915-1916. In view of the fact, however, that there are only about 75 of these classes in the greater city, the number of children receiving treatment at the present time constitute only a small percentage of those whose condition would warrant instruction in such classes. The further extension of these facilities was hampered for a time by the difficulty of securing arrangements for the provision of meals which were given to the children. To expedite the development of the movement, the Committee on the Prevention of Tuberculosis of the Charity Organization Society has recently abandoned the practice of providing the children with food in the morning. Another reason which prompted the Tuberculosis Committee to do away with feeding was the high cost of the service and the discovery that many parents neglected to provide the children with breakfast when they knew that the children would be given a meal at school.

The classification of cases in the fresh air classes is shown in Table V.*

It will be noticed that the cases of malnutrition in the fresh-air classes constitute a very large percentage of the total number of children thus being

*Eighteenth Annual Report of the New York City Superintendent of Schools on Special Classes, 1915-1916, p. 21.

cared for. In 1914-1915 there were 312 malnutrites out of a total of 726 children; the following year the percentage was still larger as there were 819 out of an enrollment of 1,830. In view of the large prevalence of malnutrition in our school population it is evident that the number of fresh-air classes should be multiplied a hundred fold and should be established in connection with every public and parochial school.

TABLE V.—TYPES OF CHILDREN IN THE FRESH AIR CLASSES.

	1914-5.	1915-6.
Exposed to tuberculosis at home.....	234	356
Healed and arrested tuberculosis.....	60	190
Cardiac lesions.....	79	246
Chorea.....	41	148
Malnutrition.....	312	890
	726	1830

B. Tuberculosis Preventorium.—A very efficient means of upbuilding the vitality of children coming from families in which there is tuberculosis has been established through the agency of the Tuberculosis Preventorium for Children. Hundreds of debilitated children with tuberculous diathesis are cared for annually in the preventorium situated at Farmingdale, New Jersey, where they are kept for about six months on the average, and where they are given medical, educational, and nutritional care of a very high order. There are a few other minor institutions of that character, mainly denominational. There is undoubtedly a need for further extension of this movement either in connection with Farmingdale or independently.

C. School Lunches.—Another remedial measure of established usefulness is the lunch service in the public schools. The service was inaugurated several years ago in one or two schools in Manhattan by a small group of interested persons and afterward taken over by the Association for Improving the Condition of the Poor with the distinct intention of getting the service well organized and later inducing the city to undertake it as a part of the regular school program. This is still the policy of the association. The New York School Lunch Committee exercises control over the lunches in the public schools of Manhattan and the Bronx, and there is another committee to take care of the school lunches in Brooklyn.

The "school lunch" has its interesting history and philosophy and its own administrative problems. The practice of feeding children at school is not a new venture in the educational world. It has been known in Germany since the end of the eighteenth century, and it was introduced in France in 1849 and in England in 1866.⁴ The difficulty of instructing children who suffer from inanition has been recognized by schoolmasters, and arrangements have been made to provide gratuitous meals at school, paid for from public funds.

From the very start the American practice has been different in principle. Emphasis has been laid on the fact that the school lunch service should not smack of charity. Many children, even those of the very poor, bring several coppers with them to spend during the lunch recess. In the absence of a lunch service at the school, they spend their pennies in purchasing candies and other eatables of the pushcart vendors outside the schools. The same

coppers can buy wholesome and nutritious food at the school if the service is properly organized. From the very outset it was planned that the service should not be limited to indigent children, but should be open to all on equal terms. The malnourished, indigent children receive meal tickets from the teachers, the cost of the gratuitous meals being covered by a special fund.

The theoretical one-hour lunch recess, which in practice amounts probably to not more than 45 minutes, in view of the time lost in leaving school and waiting in line on return, is too short to enable many children to go home for lunch, and eat it without injurious haste. In many homes the mothers are engaged in outside work, and the children stay around the school building during the lunch recess. Frequently inclement weather keeps children from going home. All these causes combined create a demand for lunches at school on the part of a large number of children. The originators of the movement in New York counted on this large demand for establishing the service on a democratic and nearly, if not fully, self-supporting basis.

The same principles underlie the school lunch systems in the other American cities. The service has been widely introduced in all parts of the country. In Philadelphia the experiment has been tried out very successfully, and in 1915 the service was taken over by the Department of Education. At that time the School Lunch Committee of Philadelphia published an elaborate report⁵ setting forth the results of their experience. That "more lunches are served at the ten o'clock recess than at any other time" is one of the findings of the study. The superintendent of schools of Philadelphia is of the opinion that it is advisable to institute a lunch system which would give the children an opportunity to have mid-morning lunches, as many come to school without breakfast, or have eaten so early in the morning that they want something to eat at about ten o'clock. In a recent investigation made by the Department of Superintendence in one section of Philadelphia, it was found that 8 per cent. of the children came to school with no breakfast and 60 per cent. with insufficient breakfast.

The other findings of the Philadelphia committee are likewise very instructive. One of them is that the *a la carte* plan is more popular than the *table d'hôte*. That is, the children prefer a choice of three one-cent units to a three-cent combination. The average expenditure of a child at the school lunch counter was one dollar and twenty cents per year. The other finding was that the lunch sales are greatly affected by the weather and the season of the year, and do not follow the curve of school attendance. During the winter months the sales are high, regardless of school attendance. The five-year experiment fully established the fact that "children will buy wholesome food at school if given the opportunity," and that the service can be put on an almost self-supporting basis."

Since the Philadelphia Board of Education assumed control over the lunches in elementary schools it has opened 25 additional counters in as many schools, and placed them under the same supervision as the lunch services in the high schools. The director of the Department of School Luncheons reports that during 1916 the sales at one cent a portion cov-

ered only the cost of food and the services of the workers. The deficit was met with the profits realized from the lunches in the high schools. During the year approximately 33,000 children in the elementary schools and 15,000 pupils in the high schools availed themselves of the 50 school lunch counters at either the morning recess or during the noon lunch hour. They paid in \$150,000, of which 66 per cent. was expended for food, 32 per cent. for supervision and wages, and 2 per cent. for repairs and replacing of equipment.

The New York School Lunch Committee maintains the lunch service in 35 elementary schools situated in the more congested parts of Manhattan and the Bronx, and proposes to enlarge it as soon as additional funds are raised for the purpose. About 20 per cent. of the children in the schools where the services have been instituted avail themselves of the lunches. The service is operated at a loss. The money paid by the children covers only the cost of food. The deficit is met partly by an allowance from the fund donated to the Association for Improving the Condition of the Poor by Mrs. E. M. Anderson for social welfare, and in part by voluntary contributions of persons interested. The city contributes the necessary space, and also the equipment. Formerly each school had its own kitchen, but it has been found more economical to prepare the food in central kitchens and distribute it by trucks. At the present time there are four central kitchens, one capable of supplying fifty schools, located in an abandoned school building at Delancey and Tompkins Streets, and three small ones located in other sections of the city. Two automobile trucks distribute the food.

The lunch service in each school is in the charge of two women, one serving the soup and washing the dishes, and the other helping to serve and acting as cashier. Usually one or two of the school children assist in selling. In schools where the attendance is very large an extra paid helper is added. The women workers, who work eight hours a day, receive \$7 per week. Their time is frequently divided between different schools. The cashiers receive from \$3.50 to \$5 a week, and work from 10 A. M. until 2 P. M. The rate of compensation and the hours of service depend upon the conditions in the various schools.

The food served to the children is examined as to its quality, and is prepared under carefully supervised sanitary conditions. The menus are prepared by a trained dietitian. Before a dish is authorized the dietitian must be satisfied that it does not offend religious or racial prejudices, that it is not below the desired standard of food value, and that the essentials of proper balance of constituents is maintained in the preparation of the food. The children are free to select the foods, but all must buy a bowl of soup before they can obtain anything else.

In Table VI are some of the combinations of food which the children were able to purchase several years ago at a cost of three cents.⁷ Now the same combinations cost six cents.

The school-lunch experiment in New York has fully demonstrated the value and possibilities of a rationally organized service for the benefit of school children. It has been successful as far as it has gone, but owing to the limitations imposed by the lack

of adequate funds it has not been extended to as many schools as it should have been, in the best interests of the children. The selection of the schools could, perhaps, have been improved in some instances, and more emphasis laid on the educational side than has been done. The New York School Lunch Committee clearly realize the limitations of their work, and are desirous of having the city take it over and expand it in accordance with the well-recognized needs. The school authorities have always favored the school lunch, and regarded it as a desirable adjunct to the school organization. They appreciate that inadequate nourishment retards the educative process. The cost of reeducating children who fail in their studies because of undernourishment will undoubtedly more than cover the possible deficit which the city may incur by maintaining a lunch service in the public schools which demand it. In principle, selling food at cost to school children who are in need of it does not differ from providing milk at cost for children registered in the municipal Babies' Welfare Stations. A study⁸ made by Miss M. E. Bulkley in England shows that the effect of the school luncheon on the school children was most beneficial. "Whether we consider the improvement in physique, mental capacity, or manners, there is no doubt that the provision of school meals has proved of the greatest benefit."

There is a need of maintaining the lunch service in 100 of the 248 public schools of Manhattan and The Bronx. This would mean providing equipment for 65 additional schools. The cost of such equipment is about \$500 per school. In addition, four new central kitchens would probably be required and at least two additional automobile trucks. Funds would have to be provided to pay the wages of the 250 lunch and kitchen attendants, cooks, drivers, and overseers. The installation of the lunch services in the additional schools, the equipment of the new central kitchens, and the buying of two new trucks would probably mean an outlay of \$80,000. The cost of personal service would amount to over \$100,000 annually. To this should be added the cost of upkeep and repairs and the rental charges for the central kitchens. It is highly improbable that with the present high prices of foodstuffs the penny contributions of the children could do more than cover the cost of food. All the other expenditures of the service will have to be met by tax funds, if the city decide to make it a part of the school organization.

D. Baby Welfare Stations.—Realizing that a

great deal of malnutrition is due to ignorance, early in 1917 the Health Department of the city determined to furnish the mothers registered in the Baby Welfare Stations with practical instructions in cooking cereals and other foods and with advice as to how best to utilize a dollar's worth in buying wholesome and nutritious food. The nurses of the Baby Welfare Stations were given preliminary instruction by dietitians, and afternoon classes were started in the Milk Stations. The response is reported to be very encouraging. The women come regularly, and contribute small amounts to a fund for the purchase of the materials. The cooked foods are divided among them and taken home. Through these classes many women learned for the first time the taste of cereals, as well as the method of preparing these foods. The demonstration cooking classes in other cities are reported to have gained similar success in enlarging the dietary of the people by introducing cereals.

E. Diet Kitchens.—To meet the demand for cheap cooked food in the poorer districts of the city, kitchens have been opened in connection with settlements and other organizations. The People's Kitchen at Twenty-eighth Street and Tenth Avenue is serving several hundred meals daily. Many women employed during the day purchase the food for their households at these kitchens.

F. Fresh Air Funds.—Another important agency which aims at upbuilding the children is the fresh air funds and camps. Thousands of children are taken to the country or seashore during the summer for short periods, usually about twelve days. This excellent charity is doing very effective work in giving the children an opportunity to enjoy the benefits of fresh air and good food. The period of stay, however, is very short, especially for the children who are very much run down. It seems desirable that arrangements should be made for a longer stay for those children whose condition is considerably below normal. In addition to the extension of time at these camps, more control should be exercised over the diet and hours of sleep of the children than is being done in some of the camps.

G. Education.—The importance of proper instruction in personal hygiene and right living as a powerful counterforce to malnutrition has been well recognized, and educational campaigns have been carried on along these lines by public and private agencies. Their efforts have thus far failed of tangible accomplishment in view of the inertia and strongly entrenched habits of the various groups composing our population. A great deal remains to be done in the educational field.

In this connection it may be of interest to refer to a study made by Mr. Frank A. Manny of a number of malnutrition cases in the Gramercy District. The study revealed the fact that malnutrition is more prevalent among children of native than among children of foreign-born parents. It might be worth while to follow up these findings with a more extensive study and ascertain the reasons for the condition if it obtain generally.

3. *Need of Coordination.*—If the various efforts which have been put forth to remedy the malnutrition condition among school children were properly correlated and directed, and if the cases were segregated according to a well-devised plan and the

children of the wasting type eliminated for treatment in hospitals, a maximum of result could be accomplished with a minimum of expenditure. At present the various efforts being put forth lack a proper measure of coordination. A representative committee of the most important organizations interested in the problem could probably undertake such a task to advantage.

RECOMMENDATIONS.

1. That a wide educational campaign including practical instruction in cooking be instituted by the various agencies interested in the promotion of welfare of children.

2. That special lectures on proper nutrition and general hygiene be given frequently in the elementary and high schools, public and parochial. Printed dietetic instruction might to advantage be given to school children in connection with the lectures.

3. That the Health Department be urged to concentrate the attention of the Division of School Medical Inspection on the problem of malnutrition.

4. That school nurses be instructed to make frequent and careful follow-up visits to malnutrition cases and to co-operate with the special clinics.

5. That the schools be provided with easily accessible scales for use in connection with the periodic medical inspections as well as the reexaminations.

6. That the Bureau of Child Hygiene publish annually the data bearing on the physical growth of the school children.

7. That the useful work done at some of the clinics of the city, where special classes have been formed for undernourished children, be extended to the general dispensaries of the city. Such classes should be organized in connection with the pediatric departments of the dispensaries and the hours arranged to meet the convenience of the school children as far as possible.

8. That effort be made on the part of the health authorities to cooperate systematically with the various civic and social service agencies, as well as clinics, to reach the children of pre-school age between two and six years.

9. That the school authorities be impressed with the need of the further extension of the fresh air classes, and that effort should be made to bring all the children in these classes in relation with the nutrition clinics.

10. That the midday recess be made long enough to allow the children to eat their luncheons with less haste.

11. That the school lunches be extended. If private means are not available to assure the desired extension, it should be taken over by the municipality.

12. The service should be placed under the control of a special division of the Department of Education and be made self-supporting, at least as far as the cost of food is concerned.

13. Control should be exercised in connection with the sale of the lunches so as to insure a proper selection of foods and the attendants should make note of children who appear to be poorly nourished and refer them to the school nurses.

14. That the teachers should be impressed with the prevalence of malnutrition and be instructed

to observe the children with reference to their nutritional condition. Children with pronounced malnutrition symptoms should be referred to the school doctors and nurses.

15. That the number of community and demonstration kitchens be increased, and that special cereal kitchens be established in connection with them.

16. That an effort be made to send all the children suffering from malnutrition to camps and fresh air homes during the summer, to be kept there for longer periods of time than are usually allowed. Efforts should be made also to secure an adequate control of the feeding and the sleeping accommodations in the camps.

17. That a special committee representing the various civic and public health agencies of the city be organized to promote a movement for the proper nutritional care of children, and to correlate the various endeavors being made along these lines in the city.

THE PSYCHOPATHOLOGY OF SELECTIONS OF VOCATIONS;*

PRELIMINARY COMMUNICATION.

By A. A. BRILL, Ph.D., M.D.,

NEW YORK.

ASSISTANT PROFESSOR OF PSYCHIATRY, N. Y. POST-GRADUATE MEDICAL SCHOOL.

THE reason why I object to certain types of fairy tales is because fairy tales are offshoots of archaic thinking originating in antiquity, and because they are products of unconscious wishes symbolically representing those primitive impulses which the cultured being must learn to repress and sublimate in order to fit himself for modern life.¹ Progressive civilization depends on the harnessing and controlling of the forces of nature as well as the forces of the individual, and in directing these forces into useful channels. A fairy tale, or a story that stimulates any of the partial impulses or components of sex in children, may impede or arrest the normal control of the individual's energy. Sooner or later every normal human being must give up many of his natural prerogatives and be-

come part of the society he lives in. He must renounce many of his individual desires and must exert continuous effort for the common weal. That is, every individual must contribute something to the society he lives in by adding something useful to it. We may designate such contributions as work.

In the progressive development of culture this mode of activity became more and more complex. At first there were almost as many vocations as men, but as time went on it was found necessary that many persons perform the same kind of work. Instead of one tailor or doctor or musician there had to be many tailors, many doctors, and many musicians. In other words, every individual has been allowed by society to live through some of the pleasure principles, but he has been forced to adapt himself to the principle of reality. From our psychoanalytic knowledge we recognize this process as sublimation. Every activity or vocation not directed to sex in the broadest sense, no matter under what guise, is a form of sublimation.

Now, is the form of sublimation followed by the individual a matter of accident; in other words, is the selection of vocation a matter of chance, or is it governed by definite laws? The average person seems to consider the selection of a vocation accidental or at least something that is quite impersonal. He usually assumes that given certain qualifications, physical or mental, or both, a person could undertake any kind of work or vocation. This view is evidently held by parents who usually think they are best qualified to select their children's vocation, and by professional vocational guides who have reduced it all to a sort of mathematical formula. They examine the person, discover some of his attributes, and then feel presumptuous enough to tell him what he is fitted for.

Such procedure may be good enough for defective persons whose power of sublimation is poor in any case and whom a certain amount of suggestion can influence at least for a time. But does a normal person need such advice and does such advice help him? Investigation shows that the normal individual needs no advice or suggestion in the selection of a vocation, he usually senses best what activity to follow, and, what is more, he is invariably harmed if advice is thrust upon him by a person of authority. For it is known that all our actions are psychically determined by unconscious motives, that there is no psychic activity which does not follow definite paths formed in the individual since his childhood, and as work or profession is nothing but a sublimating process in the service of hunger and love we may assume that it also must be guided by the individual's unconscious motives. Investigation has convinced me of the truth of these assumptions.

When we ask a person why he follows a certain vocation he usually answers that he does not know, that he just drifted into it accidentally. Occasionally he answers that his grandfather and his father performed the same line of work and that he followed it. On applying the psychoanalytic method, however, one usually finds some hidden reasons for the particular activity. For years I had investigated in this manner among patients, friends, and strangers, and though my findings are not com-

*Read before the New York Psychoanalytic Society on March 27, 1917.

plete I feel that I can furnish a preliminary report.

The motives which actuate one to take up a certain vocation vary with the person, that is, every vocation is individually determined. My first investigation naturally began with physicians. I asked of my confrères why they took up the practice of medicine as a vocation and from the many answers obtained I shall mention some.

Dr. W. stated that since his early childhood he had been surrounded with doctors who were endeavoring to cure him of a paralyzed limb, the effects of infantile paralysis, and as they could not help him he decided to become a physician and cure himself.

Dr. A. recalled that as a child he suffered from boils or carbuncles and was taken to the doctor by his father. The doctor was very brutal to him, and very inconsiderate and almost insulting to his poor father. As a child he could not understand his father's humility in the presence of the brutal doctor, as his father's behavior was quite different in his own home. This impression remained permanently fixed on his mind. Whenever he was punished by his father he thought of the doctor before whom his father trembled, and as a small boy he secretly wished he were a doctor. When he became of age he realized his wish.

Dr. B. had no idea why he chose medicine as his profession, but finally recalled a scene from his early childhood. He overheard a conversation between his mother and another woman; the latter looking at him asked his mother the month of his birth, and when told that it was the month of October she dryly remarked, "Poor boy, he will be either a doctor, a butcher, or a murderer. He will have to shed blood." As he did not care to adopt the last two vocations, he became a physician.

Dr. C. told me that as a boy he lived near a slaughter house, and often witnessed the killing and skinning of animals, which greatly fascinated him. Since the age of eight years he had not seen the slaughter house, and these scenes entirely vanished from his mind, but when at the age of sixteen the teacher of physiology demonstrated the circulation of the blood in the frog he became very interested and decided to study medicine.

Dr. D. was the son of a horse dealer who was also interested in veterinary surgery. His father urged him to become a veterinary surgeon, which he set out to do, but changed later to human beings.

Dr. E. was the son of a butcher whose ambition it was that the son should follow his vocation. The latter, however, insisted upon studying medicine and became a learned anatomist.

In all these cases the sado-masochistic components were first accentuated—in *Dr. W.* through his own suffering, and in the others through early impressions—and later sublimated in the profession.

The woman who associated the doctor (surgeon) with the butcher and murderer was not so far from the mark. All these activities are based on the sado-masochistic components, it is only a question of adjustment. The surgeon and the butcher have both conquered their sadistic impulses and sublimate the same for useful purposes. The former representing a higher state of mental evolution becomes a direct savior of human beings, while the latter, not so much endowed mentally or perhaps having lacked the opportunities for further mental development, still helps mankind by butchering the animals which furnish its meat supply.

Barbers, too, are often dominated by a strong sadistic trend. Not so long ago the barber used to pull teeth, perform venesection, cupping, and other minor surgical operations. The barber's pole was originally a white pole sprinkled with blood.

The professions of prize fighters, wrestlers, bull-

fighters, warriors, and mighty hunters are direct descendants of pure sadism, and the need for the sadistic outlet is well shown by the popularity of these vocations. Those who witness a prize fight soon observe that the whole audience, and particularly the votaries of the manly art, actually participate in the fight. One of my patients told me that whenever he goes to a prize fight he has to sit apart from everyone, for when the prize fighter, who is his favorite, strikes he has to imitate him. He got himself into trouble many a time for hitting his neighbors, he simply could not control himself, and to avoid this he has to sit away from the other spectators. Others do not actually strike their neighbors but they shout, yell, and mimic the actors; in other words, they identify themselves with the fighter and in this way give vent to their own sadistic feelings.

Some of the mechanisms are quite different, thus I know three physicians who selected this profession because as children they were jealous of the family doctor, who, they imagined stood in greater favor with their mothers than their own fathers. Quite a number of the sons of my lady patients whom I treated successfully have announced their intention to study medicine and take up my specialty. There is a tendency on the part of the sons to rival their fathers or any other man whom their mother admires. The last mechanism is also observed in other vocations. I know two sons who became real estate agents in order to outdo the man with whom their mother was in love.

The profession of law is often taken up as a reaction to a dishonest act committed in childhood or early boyhood by oneself, by parents, or by some immediate member of the family, as brother or sister. Such persons are usually scrupulously honest lawyers and judges, as unconsciously they always feel that they are suspected and that they have something to atone for. Quite often it is an unconscious effort to obtain justice for oneself as a result of an injustice experienced in childhood.

Mr. C., a very prominent jurist, had no idea why he took up the study of law, but examination revealed the following facts: He was brought up in a religious New England atmosphere. His mother was rather nervous, and kept her husband and children in a very repressive state. The Mayflower spirit hovered over everything. She particularly objected to smoking, and for years quarreled with her husband about it, until he was forced to give up this luxury. Her two boys were constantly subjected to all sorts of restrictions. One day, while waiting with other children in the dressing room of a dancing school, they noticed a burning cigarette left by the dancing master. The older brother, noticing the burning cigarette, which stood for one of the strongest taboos in his home, conceived the temptation to violate it, and not having the courage to do it himself, he turned to his younger brother and said, "Charles, I dare you to take a puff from this cigarette." "I will take one if you will," answered Charles, and on being assured that the older brother would follow him in this transgression, he bravely inserted the cigarette into his mouth and took the puff. His older brother thereupon lost his courage and refused to follow suit. And what was more, in order to atone for his evil thought, he told his parents of what Charles was guilty. One can hardly picture the fear, remorse, mortification, and last, but not least, the sense of injustice experienced by the little boy when he was denounced to his parents. The mother was terrified at her son's crime, and called him to account for it. Charles experienced a double feeling; to confess would be facing his mother's terrible wrath, and to lie would

be facing the wrath of heaven. He chose the latter and stoutly denied his guilt. To settle the matter the parents asked him whether he would take an oath on the Bible that he did not commit this crime. Charles hesitated just a few seconds and then stood ready to take the oath. It seems that the parents suspected that he was guilty, or they feared to use the holy Bible in vain, so that instead of bringing in the holy book they brought in the Bible stories, upon which Charles swore that he did not take the puff. The parents probably soon forgot the episode, but Charles retained an everlasting impression of it. For a long time he felt like a person guilty of an enormous crime against God and his parents, and constantly anticipated some terrible retribution; on the other hand, he felt that a great injustice was done to him by his brother, who first inveigled him into committing this evil act, and then betrayed him. In time this episode was forgotten, but the small boy became thoughtful and serious minded; as he grew older he became a champion of his oppressed classmates and gradually decided to become a judge. When he graduated from college he took up the study of law and realized his wish.

What was just enumerated was discovered during the analysis of a stereotyped dream which appeared on two occasions while the dreamer was under an anesthetic, the second time after an interval of twenty years. The dreamer imagined that it was the Day of Judgment, and that he stood before God, who asked him questions; although he knew the answers he refused to give them and was jeered by the multitude. God in the dream was his father, and being examined on the Day of Judgment referred to the episode just related. The father in the dream as well as in daily life is often substituted by the Governor, the Mayor, and by God himself.² Mr. C., who is now about fifty-five years old, had no conscious knowledge of the cigarette episode and the part it played in his life until his dream was analyzed. When he finished his story I remarked that there was one other vocation that he might have taken up, the ministry, because in my experience this vocation is often followed by persons who unconsciously feel remorse for some crime committed in childhood or as a reaction to temptations in later life. He confirmed my statement by telling me that he was in doubt as to which of the two vocations to take up, and if it were not for the fact that his religious feelings underwent a great change during his college years he would have become a minister of the gospel. He was undecided about it until he graduated from college—it was always a question between the ministry or the law.

Unconscious and sometimes conscious feelings of guilt and remorse as a reaction to real or imaginary sins are often the basis of theological callings. This mechanism is clearly seen in such religious groups as the Salvation Army and some Missions. If one attends such religious meetings one invariably hears confessions such as, "I was a thief and a low sinner until I saw the light of the Lord; two years later I was a backslider but again I found Him," etc. Some of the converts fluctuate all the time between heaven and hell. Here the maladjustment is so marked that sublimation is imperfect or almost impossible; this accounts for the chronic backsliding and the repeated changes from one religion to another. Only a few months ago the daily press reported the case of a clergyman who changed for the third time from one denomination to another.

I know a similar case of a man who fluctuates

between fervent Evangelism and extreme Atheism. He is a morbidly religious person who is making desperate efforts to adjust himself, and depending on the reaction of the time he either preaches the gospel or the non-existence of God. I was also impressed by the number of dissatisfied and struggling homosexuals who follow religious callings.

Sublimation of infantile exhibitionism³ often impels one to follow the stage, the army, or the vocation of life saver. The actor and the professional soldier are sublimated exhibitionists *par excellence*; the latter is also unconsciously dominated by a strong aggressive component. The aggressive component which under certain conditions changes to sadism is found in the sexuality of most men. "It is a propensity to subdue, the biological significance of which lies in the necessity of overcoming the resistance of the sexual object by actions other than mere courting." This component is seen throughout life in its sublimated form, one notes it in the aggressive business man, in the lawyer, in the satirical speaker and in its accentuated form in the soldier. Among the first games of boys one invariably finds the playing of soldier, and the need for such outlets is readily seen in the popularity of the Boy Scout movement, and the admiration that has been bestowed on soldiers from time immemorial.

Acting also belongs to the earliest games of children. In fact most playing of children is acting. It is known that a great many nervous people are good actors; they are natural actors. Hysterical persons can imitate almost anything; they are the best tragedians as well as the best comedians. And if we consider the nature and mechanism, namely, the inability to adjust or fix properly one's libido, we can readily understand the psychology of the actor. The actor utilizes this very inferiority as a sublimation. Actors are persons who are usually unable to fix properly their libido. Due to some unconscious disturbance their emotional transference is more or less inhibited, so that they are unable to develop fixed characteristics; they remain more or less infantile and are therefore able to identify themselves with the different characters they represent on the stage; they are still mouldable, as it were. That accounts for some of the characteristic traits of the actor. I refer to the sexual maladjustment as evinced in uninhibited morality and marital unsteadiness which have been attributed to stage folks in all lands and at all ages. To be rigid or at least regular in the sense of following the dictum of society in one's sex life presupposes a well adjusted and fixed libido. Now I do not wish to imply that the actor is to be considered inferior because he manifests this maladjustment of his love life; on the contrary he has the courage to put in operation what the average person secretly desires. That is why we admire the actor, and that accounts for the popularity of plays which deal with the primitive impulses. They offer us a mental catharsis, we cry and laugh at the play because we identify ourselves with the actor, to wit, with the hounded rogue or ideal hero, whom he represents. The actor's identification with the stage character is well illustrated by the following story. An admirer of the great actor Booth, after witnessing his wonderful performance of King Lear,

asked the famous tragedian to explain the secret of his skilful rendition of this character. Booth turning very abruptly responded, "Sir, I am Lear."

It is due to the same mechanism that only few great actors have ever produced original works that could lay claim to individuality. They are so used to identify themselves with their stage characters that they find no time to develop a steady and fixed character of their own. For the character of a person is nothing but the sum total of one's past impressions.

My own investigation with life savers convinces me that most of them take genuine delight in their vocations mainly because they love to display their well developed muscles. Professional athletes and "sports" are dominated by the same exhibitionistic impulse, most of the latter, however, unable to exhibit themselves, gain pleasure by identifying themselves with the actors (ball players, fighters, etc.).

Some of the vocations can be traced to very early infantile sexual traits. Thus I know of a maker of optical instruments, a successful manager of a big camera department, and three photographers who were punished in childhood for evincing a strong curiosity for sexual looking, and although they did not become *voyeurs*, they all manifested a strong tendency for looking. I have reported the case of a man who displayed in early childhood a strong perverted impulse for odors,⁶ who became a successful perfume dealer, after he was a failure in two other vocations. Unconsciously such people take up the vocations that gratify them in a sublimated form. The reader need not be surprised and shocked merely because some people who are doing useful work merged into it through sexual impressions of childhood. There is nothing wrong about it. Some of the most sublime institutions in this world had their origin in sex.

In analyzing a man who became rich from an invention, or rather an improvement of patterns for ladies' apparel, I found the following facts: He was brought up in a small settlement in very poor surroundings. His father was unambitious, apparently not a very strong character, while his mother, to whom he was very much attached, was a very hard working woman who had a constant struggle to keep the wolf from the door. She was rarely able to save enough money to buy new clothes for the children and herself, and as a little boy he was often moved to tears when she bewailed her sad lot. It was the strong wish to grow up and work for his mother which later guided him unconsciously to occupy himself so assiduously with things relating to women's apparel through which he made his fortune.

Some selections of professions are quite puzzling. One wonders why some people take up the heavy brass instruments or the bass-drum in music. For the information of some it may be said that the players on these instruments usually have as much knowledge of music as any member of the band. One might therefore ask why they prefer instruments that can be used only in conjunction with a band and which offer little if any outlet in any other way. I have not had the opportunity to study many such people, so that I am not offering anything conclusive. I know two drum players and two saxhorn players.

Mr. T., a drummer in an orchestra, told me that as a little boy of 4, 5, or 6 years he was very anxious to have a drum; the neighbor's boy received one for Christmas and he begged his father for one and cried for it, but the latter either did not wish to buy it for him or was perhaps too poor to do so. One evening the neighbor's door was open and no one seemed to be home; he walked quietly into the house and stole the drum. He hid it for a while, but as he could not resist the temptation to beat on it he was soon caught with the goods. The punishment was severe and produced a very strong impression. At the age of seventeen years he began to study the violin, and a few years later he joined an amateur orchestra, playing second violin. A vacancy for the drummer's place then occurred and he volunteered to fill it. In a very short time he became such an accomplished player on this instrument that he obtained a lucrative position in a big orchestra.

Mr. X., the other kettle drum player, was very fond of music and studied it for years. He, too, volunteered to take the position of drummer in a band and has played on this instrument ever since. Mr. X. came to me for treatment because of bashfulness. He had always been a very seclusive and reserved person afraid to speak to people. It was impossible for him to put himself *en rapport* with anybody. He became tongue-tied whenever he came in contact with people, men or women. When he first came to this city he refused to live in a boarding house because he was afraid he would have to sit at the same table with people who might talk to him. Before taking up music as a profession he lost his position in an office because he was unable to talk to the manager of his department. Here the drum fits in well with his nature; the drum is not an instrument that talks along fluently with the other instruments, as, *e.g.* the violin or clarinet; though it is a part of the band it is nevertheless more or less aloof in its behavior and it can always be heard when it speaks. In the case of Mr. X. it served as a compensation for his enforced quietude.

The players on the heavy brass instruments showed similar mechanisms to the one found in X. One observes that people playing on drums, basses, or heavy brass instruments are not of the same type as those who play the first violin, and are altogether different in makeup from those who lead the band. They are often people who for some reason or other must stand away from the crowd, who are not very good "mixers" but would like to be.

I have spoken to a number of people who were rubbers in Turkish baths. I found that in some cases the vocation went back to the infantile desires for touching, in others it was distinctly pathological, and still others have taken up this vocation because it alleviates their own physical ailments. I have in mind one man who has been a "rubber" for about twenty years. He told me that he suffered from rheumatism, and was told that Turkish baths would help him; as his aches diminished through the baths he decided to take up some occupation in the baths and became a rubber.

A few street cleaners have also been examined. Some were seen by me, and a few by former patients who kindly volunteered to assist me. There seem to be two types of street cleaners, some who

are quite old or incapacitated to an extent that they are unable to follow their former vocations, and others who select street cleaning as a vocation of preference. The latter are usually clean-cut men of about 35 years and one wonders why they should be attracted to street cleaning. Of the few examined, some seemed to have retained the infantile coprophilia and, like children, liked to wallow in dirt. One of my friends brought me a report of a man of about 35 years, a street cleaner, who described the difficulties he had to encounter to obtain this position; that he had to pass examinations and had to get some political influence, etc., etc. This man distinctly stated that he "loved" his work because "I love to see the water flush the streets and clean them through and through." His whole life seemed to be in his work, as he described it. This man recalls Boitelle by Maupassant, who "made a specialty of undertaking dirty jobs all through the countryside. Whenever there was a ditch or a cesspool to be cleaned out, a dunghill removed, a sewer cleansed, or any dirt hole whatever, he was always employed to do it." Dr. Karpas, from whose interesting paper I am quoting,⁶ states: "Boitelle was disappointed in love—he was not allowed to marry a negress with whom he was deeply in love. Thus his ungratified wish—to marry a negress who was forbidden him by his parents and by society—found a substitute in the selection of a particular vocation which was likewise dirty and disagreeable to society."

One of the street cleaners who came under my observation presented almost a similar mechanism. He was an able-bodied man of about 40 years who could give no reason for selecting this vocation. When asked about it, he said it was "as rotten and dirty as any other—what does it matter what you do?" He was an avowed anarchist and took every occasion to decry the rottenness of our social system. I heard him first a few years ago at a public meeting where he protested against being forced by the Street Cleaning Department to march with a dirty broom on his shoulder. He was fiery in his denunciation, to the extent of advocating violence. I was unable to enter into his intimate life, but may we not assume that his vocation was an unconscious effort to clean up the rottenness of society which seemed to trouble him so much? I have no doubt that had we been able to enter into this man's life we would have found besides some infantile determinant.

Besides the specific forms of sublimation, as seen in special vocations, one also notices certain modes of sublimation of a more or less general nature. "Only" children and first-borns, who, by virtue of their positions in the family, become domineering and officious,⁷ usually select the vocations requiring leadership, such as teachers, religious and political leaders, while the youngest child, who was bullied and intimidated by his older brothers, is generally satisfied with a subordinate position in life. I have mentioned only very few examples of the mechanism of selection of vocation that have come under my observation, but these suffice to show the forces that one generally finds behind selected vocations. There is always some psychic determinant which laid the foundation for the later vocation, and if not interfered with the individual is unconsciously

guided to express his sublimation in that particular form. It makes no difference whether a man is a financier, preacher, actor, physician, cook, or shoemaker, provided he himself has selected this vocation and was not forced into it by home environments or social conditions; he will find his proper outlet in his work and under normal conditions he will never become fatigued by it or wearied of it. Most of the failures in life are due to the fact that one tries to do what one is unfit for or unwilling to accomplish. Incidentally, I wish to say that no one ever suffers a nervous breakdown from overwork. Of course, I am not referring to breakdowns as a result of physical factors which are seen among workers in factories under unsanitary conditions, but to the so-called nervous breakdowns as a result of overwork. Strictly speaking, these maladies do not exist. When one investigates such nervous breakdowns one invariably finds that many of them belong to the psychoses; others represent well-developed neuroses which were brought to the surface by any of the provoking agents one always encounters in such maladies, and in still others one finds that the work or vocation was always accompanied by severe resistances, and that instead of representing a natural outlet it was monotonous drudgery. When one takes the history of such persons one finds that they were always more or less discontented, that they were in constant need of vacations, and were always ailing. Contented workers have to be forced to take vacations. Vacations as commonly understood are neurotic fads which adjusted persons don't want and which are of no benefit to those who clamor for them. The fact that most vacations really cause fatigue shows that their alleged purpose is just a blind. The adjusted person works for work's sake—his vocation represents a part of his "cosmic urge" and hence he is unable to stop. That answers those who are puzzled why some of our multimillionaires continue to work untiringly. It is surely not for the love of money, as most think. On the other hand, there are cases on record of men who died soon after giving up lifelong vocations.

There are also a great many failures due to the fact that people follow certain vocations for which they are mentally unfit. Such persons are usually defectives who have not enough insight into their own ability and cannot at any time sublimate properly; this is clearly seen in their love-life wherein they evince rapid attachments and just as ready detachments of their libido. They are unable to fix on either the love object or vocation; they are pathological flirts. The other failures are due to exogenous factors; not a few among those were forced into their vocations by some authority, and were then prevented by conscious or unconscious circumstances from changing to something else. Such persons merge in time into a neurosis, which is nothing but a manifestation of their inadequate adjustment, and often enough forces them to give up their work and take up something else. Unconsciously physicians have always sensed this mechanism, and for years it was customary to advise nervous patients to take up another vocation which they selected for them. Such selections were invariably doomed to failure, as no person of normal mind, even though neurotic, should be advised as to

the selection of a vocation. As in the selection of a mate, a sensible person needs no advice and wants none, and fools will fail in spite of the best guidance, for we can only do well those things that we do with our hearts, with our whole souls. The people who themselves selected their vocations, whose cases I cited, were all successful in their various callings, because their vocations supplemented or substituted their primitive components. The German expression, "Arbeit macht das Leben süß," is literally true in cases where the work represents an outlet for the individual. This is true of all vocations. Those of you who have lived abroad and frequented the less pretentious restaurants remember how proud a French or Italian cook is of his or her special dish, and how pleased the host is when his guest enjoys his meal. One can see they derive genuine pleasure from their work. I feel that the restlessness and dissatisfaction among our working classes, which often result in strikes, is not altogether due to the causes generally attributed to them. It is not so much a question of money as of emotion. Owing to the many inventions which have gradually transformed manual labor into machine work, the laborer no longer finds the same interest in his work. The shoemaker no longer makes a shoe, but as a hand in the shoe factory he constantly performs one simple thing which is of no interest to him and which soon becomes drudgery. When one compares this factory worker to the shoemaker of yore who took the measurements, selected the leather, and then put his whole personality into the making of the shoe, one can understand why the latter, as we still find him in some parts of Europe, is a much happier man.

On the other hand, I have seen many perfectly normal people who were failures in life simply because they were not allowed to follow their own inclinations. Instead of being prepared for life in general, their parents felt it necessary to accompany and guide them through every detail. Some of them struggled for 20 and 30 years with vocations which their fathers imposed upon them and stopped being failures only after their fathers' death, when they took up something which they really liked.

Carbolic Acid Injections in Meningitis.—Godlievski and Ducas tested Baccelli's method, as used in tetanus, in cerebrospinal meningitis of diplococcus origin. This treatment is followed by some relaxation of the rigidity and contractures and, in fact, the results are at times superior to those which follow lumbar puncture and serotherapy.—*Marseille Médicale*.

SOME OBSERVATIONS ON THE USE OF CARREL-DAKIN SOLUTION ON THE SERVICE OF DR. JOHN B. DEAVER, IN THE LANKENAU HOSPITAL, PHILADELPHIA.

BY J. W. BODLEY, M.D., W. H. MEANS, M.D., AND

H. E. KNOX, M.D.

PHILADELPHIA, PA.

SURGICAL RESIDENTS, LANKENAU HOSPITAL.

EVER since Carrel and Dakin brought forth the results of their experiments in the use of the hypochlorite solution in the treatment of war injuries there has been much controversy regarding its value. Recognizing from reports that the solution must have some value, its use was instituted in the Lankenau Hospital of Philadelphia.

First it was used only in small infected wounds, and later in every type of infected case. The intra-abdominal use of this solution was begun with some care. Although it has not been introduced freely into the peritoneal cavity, there has been no hesitancy in its use in walled-off abscesses, even though the walls are formed partly by bowel.

We are indebted to Dr. John Jay Reilly, Chief Surgeon of the American International Shipbuilding Corporation, for the introduction and instruction in the use of the Carrel-Dakin solution in the Lankenau Hospital. We also wish to express our appreciation to Dr. John B. Deaver for his co-operation and suggestions, and for the privilege of carrying out a series of experiments which have brought forth the following conclusions.

Understanding that the use of the Carrel-Dakin solution is still largely in the experimental stage, and finding nothing in the literature as to the use of the solution intraabdominally, these observations are submitted for whatever value they may have.

Preparation of the Solution.—In the preparation of the Carrel-Dakin solution it is of paramount importance that the available chlorine in the chlorinated lime be accurately determined. This substance, chlorinated lime, is a product resulting from the action of chlorine upon calcium hydroxide and, according to the United States Pharmacopeia, should contain not less than 30 per cent. of available chlorine. It frequently happens, however, that many of the brands of chlorinated lime on the market are well over this official requirement for available chlorine and sometimes also below it. For this reason it is absolutely necessary that each lot of chlorinated lime be estimated by volumetric analysis for its chlorine. When this is done, and it is always important that it should be done, and the ingredients are adjusted to the proper proportions, the solution will always be uniform and give uniform results.

The procedure for making the solution is very simple. If the chlorine contents of the chlorinated lime be 30 per cent. the formula should be as follows:

Chlorinated lime (30 per cent.)	154 gm.
Sodium carbonate, dried	77 gm.
Sodium bicarbonate	64 gm.

Into a 12-liter bottle put the chlorinated lime and five liters of water and shake frequently during a period of six hours; dissolve the two sodium salts in

five liters of water and after six hours add this solution to the mixture of chlorinated lime and water and shake well for several minutes. Allow to stand for at least half an hour until reaction is complete and then siphon off the supernatant liquor and filter through paper. The solution, undiluted, is then ready for use.

When the chlorine content of the chlorinated lime is above or below 30 per cent., the proportions of the three ingredients entering into this solution must be increased or reduced accordingly. To avoid the necessary calculation that this entails, Daufresne has prepared the following table:

QUANTITIES OF INGREDIENTS FOR TEN LITERS OF DAKIN'S SOLUTION.

Titer of Chlorinated Lime.	Chlorinated Lime, Gm.	Anhydrous Sodium Carbonate, Gm.	Sodium Bicarbonate, Gm.
20	230	115	96
21	220	110	92
22	210	105	88
23	200	100	84
24	192	96	80
25	184	92	76
26	177	89	72
27	170	85	70
28	164	82	68
29	159	80	66
30	154	77	64
31	148	74	62
32	141	72	60
33	140	70	59
34	135	68	57
35	132	66	55
36	128	64	53
37	121	62	52

It would be well to take the titer of this solution occasionally. The same substances that are used for determining the activity of the chlorine in the lime are used for this purpose.

To 10 mils of the finished solution add 20 mils of a 10 per cent. solution of potassium iodide and 2 mils of acetic or hydrochloric acid. Measure into this mixture, drop by drop, from a burette, a decinormal solution of sodium thiosulphate until decoloration is complete. The number of mils used multiplied by 0.03725 will give the weight of the sodium hypochlorite in 100 mils of the preparation.

In order to determine the alkalinity of the Carrel-Dakin solution, or note its freedom from caustic sodium, add to 20 mils of the solution 0.02 of phenolphthalein; if correctly prepared no red coloration should appear.

Estimation of the amount of chlorine in the chlorinated lime is of the utmost importance, and the method of doing this is simplicity itself. One may use the method given in the U. S. P. or the following, which is the one published by Carrel (*Journal A. M. A.*, Dec. 9, 1916; *American Journal of Pharmacy*, February, 1917). "Weigh out 20 grams of the average sample, mix it as completely as possible with 1 liter of ordinary water and leave it in contact for a few hours, agitating it from time to time. Filter. Measure exactly with the gauged pipette 10 mils of the clear fluid; add to it 20 mils of a 1:10 solution of potassium iodide and 2 mils of acetic or hydrochloric acid. Drop a drop at a time into this mixture a decinormal solution of sodium thiosulphate until decoloration is complete. The number of mils of the thiosulphate solution required for complete decoloration, multiplied by 1.775, gives the weight of the active chlorine contained in 100 grams of the chlorinated lime."

If the method described above is rigidly adhered

to, the concentration of sodium hypochlorite in the finished solution will always be exactly between 0.45 and 0.50 per cent. According to Dr. Carrel, if it is below 0.45 per cent. of hypochlorite the solution is not sufficiently active; above 0.50 per cent. it becomes irritating.

Technique.—Our method of using the Carrel-Dakin solution varies according to the type of wound to be treated. We make it a practice, however, in all cases to irrigate the wound thoroughly, removing any sloughs with forceps and scissors wherever this can be done without the risk of too great trauma. This irrigation is of value in washing out pus, loosening and dissolving sloughs.

When the Carrel tubes are used they are prepared as follows: Ordinary thin rubber tubing with a lumen of 7 mm. is cut into the desired lengths, tied at one end with silk, and for a distance of from 2.5 cm. to 7.5 cm. from the tied end fine holes are punched into the tube about 1 cm. apart. In tying the tubes care should be taken that the rubber tubing is trimmed off close to the ligature, for any superfluous tubing beyond this may cause trouble by acting as a foreign body. For the same reason long loose ends of silk should be avoided. Some of the tubes are provided with only one large perforation near the closed end, thus allowing the solution to flow directly to the bottom of the wound and there to become puddled. In some types of wounds the tubes may be covered. This covering acts as an anchor to keep the tube in a fixed position, and at the same time serving as a wet compress. The covering is made of fine Turkish toweling cut just long enough to cover the perforations in the Carrel tubes, and wide enough to be sewed around a glass tube of somewhat larger caliber than the rubber tube, over which it is then slipped. Strips of gauze wrapped around the tube answer the same purpose.

In deep wounds the tubes may be used either covered or uncovered, the wound being also lightly packed with gauze moistened with the Carrel-Dakin solution. Covered tubes should not be used in narrow wounds, where drainage is a matter of primary importance, nor where there is danger of pressure and consequent interference with the nutrition of the tissues.

When the tubes are used the solution is instilled every two hours. This is done by means of reservoirs, distributing tubes, etc., as first devised by Carrel, or by means of an ordinary glass syringe. The advantage of the latter is the simplicity and low cost.

In certain cases gauze moistened at regular intervals with the Carrel-Dakin solution may also be used. We have also used the solution as an immersion, a vaginal douche, as a mouth wash, and as a constant drip.

In all cases a daily bacterial count is made in order to observe the diminution in the number of infective or putrefactive organisms. The smears for the count are carefully taken with the aid of a uniform platinum loop and special attention is paid to have the smears of uniform thickness.

At each dressing the same preparation of the hands, instruments, etc., is employed as in a major operation.

Types of Cases.—Intraabdominal abscess constitutes the most common group of cases in which we

use the Carrel-Dakin solution, whether the abscess be appendiceal or in the uterine appendages, sub-diaphragmatic, or the result of rupture of the gall-bladder, secondary collections, etc. The method of dressing the wound at operation in these cases depends on the degree of localization of the abscess formation. In a minority of cases the abscess cavities are walled off, and in these the dressing is made at once with the Carrel tubes and the instillation of the solution is begun. On the other hand, where the walling-off process has not taken place or where it is incomplete, nature is aided by the use of the gauze packing, and sometimes by rubber coffer dams which can generally be removed in from 4 to 6 days. The abscess cavity itself is packed with gauze which is allowed to remain in place 24 to 48 hours, after which the tubes are placed in the wound and the irrigation with the solution begun. It is important when removing the gauze packing to irrigate the cavity with the Carrel-Dakin solution, as this dissolves the clotted blood and exudate, and softens and loosens the gauze from the surrounding tissues.

When the gauze is removed and before the wound is dressed, a smear is made from the pus or secretion obtained by means of the uniform platinum loop, from the dependent portions of the wound or any of its recesses. The drop is placed on a sterile slide, a thin even smear is made by drawing the edge of the second slide over the first, and the specimen is sent to the laboratory for the bacterial count.

As already indicated, Carrel tubes are now inserted, from two to twenty c.c. of the solution, according to the size of the cavity, being introduced into each tube by means either of the reservoir and distributors or of a glass piston syringe. At first the wound is dressed daily, the tubes being removed and the wound irrigated, all slough and dead tissues being carefully cut away with scissors. The tubes, after having been cleaned and boiled, are replaced; two sets of tubes are kept on hand in order to save time. The number and size of the tubes, of course, vary with the size of the wound; they should be selected so as to insure adequate and proper distribution of the fluid throughout the wound. The covering of Turkish toweling or gauze is found useful in wide or superficial wounds where there is no danger of pressure or when it is needed as an anchor. In small and deep wounds the gauze is carried to and lightly distributed on all sides of the tubes, so as to bring the solution in contact with all parts of the wall of the cavity without causing any pressure. As the sides of the cavity begin to close in the covering is removed and the uncovered perforated tube is introduced, and finally, as the wound becomes more and more superficial, the gauze alone is used saturated with the solution.

Under this treatment wounds are usually free from pus at the end of from 24 to 72 hours. The bacterial count begins to drop after 24 hours, and at the end of from five to nine days the count has usually fallen to about one organism to five or ten fields. The wound may then be closed either by suture or by drawing the edges together with sterile adhesive straps, or by placing the straps mounted with shoe hooks on each side of the incision and drawing the edges together by lacing. If the skin

edges become inverted they should be freshened before the final approximation is made.

As a rule, it is not necessary to protect the skin, but when it is hypersensitive (as a skin highly susceptible to sunburn) a hyperemia may appear and the patient complain of burning. In these cases the surrounding skin may be protected with sterile liquid paraffine.

The value of a given method is best seen when compared with other procedures. We find that in our series of 125 intraabdominal abscess cases the convalescence was shortened by a period of at least one week, as compared to the cases treated by other methods in this hospital in former years. Of this series of abscesses 78 were appendiceal, 34 tubo-ovarian, 6 due to rupture of the gall-bladder, 3 sub-hepatic following removal of the gall-bladder, 3 secondary collections, 1 omental abscess.

Pulmonary Empyema.—With the Carrel-Dakin solution, pulmonary empyemas likewise yield to treatment and recover in considerably shorter time than with the former procedure. The pus, as in the old method, is evacuated by thoracotomy, a large-caliber tube is placed in the incision, which is closed up to the tube. During the first 24 to 48 hours the solution is instilled through this tube, when the large tube is withdrawn, and the cavity then treated in the manner described for abdominal abscesses, except that irrigation is performed in the sitting posture, to facilitate the free return of the solution. Of the acute we had a series of eight cases, one being discharged at the end of seventeen days entirely recovered, secondary suture having been made on the fourteenth day. Five weeks was the longest time required for complete recovery, the average time being three weeks.

Superficial Skin Infections.—In these, or when clean operative wounds have become infected, we remove a few sutures, irrigate the wound with the solution, and insert a strip of gauze moistened with the Dakin fluid; this is repeated three times daily, and in reality represents a return to the old method of treatment with wet compresses. According to the extent of breakdown, these wounds are rendered sterile in from 24 to 60 hours, when they can be closed with a few silkworm gut sutures.

Carbuncles.—The benefits of this solution are particularly well illustrated in the treatment of carbuncles. Healing, formerly so tedious and prolonged over a period of weeks and months, takes place in 10 to 14 days. In the treatment of carbuncles with the Dakin solution the same underlying principles of surgery obtain as in other wound cavities. A free crucial incision is made and all sloughs removed. The wound is packed with gauze moistened and kept constantly moistened with the solution, the dressing being changed once daily or as often as it becomes soiled, the wound being irrigated at each dressing and sloughs at the same time removed. By means of the gauze packing the skin edges are kept free so that they may be approximated as soon as the bacterial count indicates a sufficiently sterile condition of the wound.

Infected Hand or Foot.—In infection of the hand or of the foot with diffuse cellulitis over the corresponding member we have no hesitancy in immersing the affected member in the solution. As in

other cases the infected area should be incised and drainage instituted. The tubes, usually without a covering, are put in place and about 5 to 10 c.c. of the solution instilled every two hours. Once or twice daily the part is immersed directly in the solution for from 15 to 20 minutes, according to the reaction produced. It sometimes happens that this prolonged immersion causes more or less irritation where the skin is more than ordinarily sensitive. In these instances painting the surrounding skin with boric acid ointment (melted over a water bath) or spraying it with sterile paraffin oil will materially lessen the irritation and permit a free use of the immersion treatment, particularly beneficial in this type of case.

Vaginal Douche.—Rapid clearing up and disappearance of the odor of a profuse vaginal discharge results from the use of one liter of the Carrel-Dakin solution as a vaginal douche, repeated one to three times daily. In case of unusual irritation this can be reduced by the use of an alternating douche of saline solution. Care should be used in all cases to prevent any of the Carrel-Dakin solution from remaining within the vagina.

Phagedenic Chancroids.—Marked success has attended the treatment of phagedenic chancroids with the Carrel-Dakin solution. In one case the results were so surprising that we feel justified in reporting it in detail.

The patient, a young man aged 26 years, came to our dispensary with a painful, discharging chancre situated on the frenum. He was immediately put to bed and treatment instituted with 50 per cent. solution of potassium permanganate, 50 per cent. silver nitrate in the form of the caustic stick, pure iodine crystals, and pure carbolic acid. In spite of these energetic measures the condition progressed rapidly from bad to worse, until finally the dorsal surface of the glans with the corpus spongiosum and the overlying skin became involved. At this time amputation of the penis was considered and the operation was consented to. But before resorting to this radical measure an attempt was made to treat the case with Carrel-Dakin solution, owing to Dr. Reilly's marked success in the treatment of this condition in the tropics during the past year. A thick layer of gauze was applied to the parts and held in place with a bandage, and the patient was instructed to keep the gauze constantly moist with the solution which was placed at his bedside. As the dressing became soiled, it was renewed. At the end of 36 hours the discharge had ceased entirely, and at the end of five days the use of the solution was discontinued, and the patient was able to leave the hospital on the seventh day. The process had been arrested, not however, until after the dorsal half of the glans had been sacrificed. The patient stated that at no time had he experienced any irritation from the solution, and when seen four weeks later, the result was really remarkable.

Cystitis.—In severe cases of cystitis we have found that the solution irritates the delicate mucous membrane of the urethra and the bladder, and therefore do not recommend its use in these cases.

Infected Compound Fractures.—The use of the solution in this type of case does not materially differ from the procedure described for abdominal abscesses. It is essential that the seat of infection be widely exposed so that the tubes can be passed down to the base of the wound. When, however, the wound is not so deep as to admit the use of the tubes, covered or uncovered, gauze saturated and kept moist with the solution can be packed loosely

in the cavity. In only one instance did the solution cause skin irritation, and in this, after protecting the skin in the manner already indicated, we were able to use the method with the same success as in other cases.

Crushed Members.—In the case of a badly crushed arm, hand, foot, or leg, if seen within six hours after injury, or during the "period of contamination," if the tubes are placed and irrigation begun at once and repeated every two hours, infection rarely develops, and should it supervene its character is a mild one. In one case which came to us six hours after injury the right hand was almost severed at the palm and filled with dirt and grease. After placing the metacarpal bones in perfect apposition, a Carrel tube was inserted, the wound was closed with silkworm gut, and the Carrel-Dakin solution applied. The hand and arm were placed on splints (short dorsal, long palmar) and the patient was put to bed. Five c.c. of the Dakin solution were instilled into the tube every two hours. No infection appeared and the patient left the hospital three weeks later, able to move all the fingers. He was referred to the dispensary for baking and massage and has every prospect of having a useful hand.

Observations.—Our experience with Dichloramin T has been unsatisfactory in the treatment of abdominal wounds and empyemas of the character we have described. There is reason to believe that the removal of pus and slough is very important and that this cannot be properly accomplished without irrigations, which is contraindicated in the use of Dichloramin T. In the treatment of minor infections of the extremities and superficial wounds we have seen good results and feel that it has an important place in dispensary practice.

Contrary to many observers we believe that the Carrel technique is not a complicated one. It certainly requires no more time, labor, or material than the method of treating purulent collections with drainage tubes and irrigations of saline, bichloride, or carbolic solutions. Nor is the Carrel-Dakin solution more difficult to apply than Dichloramin T. The technique of the latter antiseptic requires the careful mopping out of pus from a cavity with dry gauze and the instillation of the oil through pipettes, cannulas, or a catheter, and by sprays.

Furthermore, it requires very little extra effort on the part of the nurse while attending to her regular duties to instill a few cubic centimeters of the Carrel-Dakin solution into the tubes or on top of the gauze. The deodorizing effect of this solution is very important. Our wards since the use of this antiseptic have been free from the all-pervading colon-bacillus stench. This has a psychological effect in aiding the patients' convalescence.

Much has been said about the irritating effect of the solution on skin surfaces. This in our experience has been very slight. We have abandoned the use of gauze strips saturated with vaseline and use no protection at all except when the skin appears hypersensitive, in which case a spray of liquid paraffin is used.

The mucous surfaces appear to suffer no more than the skin, as instanced by the use of the solution as a vaginal douche.

Emphasis must be laid on the contraindication to

the use of the solution in cases where there is much hemorrhage. This is controlled as well as possible at time of operation and the solution not used until 24 to 48 hours have elapsed.

Other contraindications to the use of the solution are in infections due to the *Bacillus pyocyaneus*, upon which it seems to have no effect, and in all classes of wounds after the infection has been controlled, when it is unnecessary and has a retarding influence on granulations.

In fecal fistulæ the solution is not used, because it has been noticed that patients with this condition suffer with a great deal of discomfort, and at times pain, for three to four hours after the dressing.

From the foregoing it is plainly seen that it is essential for the success of the Carrel-Dakin solution to practise wide, open surgery. The large preliminary incision and the subsequent closing after infection has been controlled render convalescence shorter than would be the case with a more conservative method. Many users of the solution have forgotten the underlying principles of surgery and expected the solution to take the place of the aseptic scalpel.

Another cause of failure is no doubt attributable to poorly prepared solutions which do not retain their chlorine content. A well-prepared solution if kept in a dark-colored bottle should be as useful and of the same strength after three weeks as when it was freshly made.

The signal advantage of a reduced period of convalescence resulting from the use of the solution has already been emphasized. This is particularly true of cases of acute pulmonary empyema, which formerly required several months' hospital treatment, and even after that time were often dismissed with sinuses draining pus, but which to-day become pus free in ten to fourteen days, and leave the hospital in from two to four weeks. Likewise cases of carbuncle clear up more rapidly and can be discharged with a closed wound instead of a granulating one.

In not a few instances we are certain that a limb and often a life has been saved by this treatment. Although still in its early stages and no doubt amenable to modification and improvement as experience increases, we feel safe in predicting for the solution an ever widening field of usefulness, and that the names of Dakin and especially of Carrel are destined to find a place with those of Pasteur and Lister in the annals of surgery.

THE TEETH ACCORDING TO RABELAIS.

By DOUGLASS W. MONTGOMERY, M.D.

SAN FRANCISCO, CAL.

RABELAIS was a monk, a physician, and a writer, and his writings are colored, as those of every good writer are, by his station in life, even as the dyer's hand is subdued to what it works in. In a detail such as the teeth this is true in the eminently objective and realistic Rabelais.

Some of these references are the usual trite ones commonly found in literature, such as breaking four of Lucifer's teeth during a visit Pantagruel paid

to Hell,¹ or knocking the teeth down the throat in describing a fight.²

Rabelais also used the same metaphor as indicating a difficult matter, as "the devil himself could not get his teeth into it,"³ or as headlong running away, as when he speaks of controversialists as taking the bit in their teeth,⁴ or as indicating great strength, as when Panurge tells Pantagruel that he has more strength in his teeth than Hercules.⁵

Many other references to the teeth are, however, very interesting, as throwing into relief some custom of the Middle Ages, or for their medical interest, or for the fun that is in them, as Panurge's remark that there is no greater pain of the teeth than when the dogs are after you. Panurge made this remark in relating his escape from Constantinople, where he was pursued by the scavenger dogs of the city.⁶ This was a good piece of local color, for these dogs were a regular institution in medieval cities, and were a vicious lot. They went about in bands, and acted as scavengers and general freebooters. Sir Michael Foster, in his charming book, "The History of Physiology," relates an amusing incident in the life of Vesalius, the great anatomist, which occurred about the year 1533, and therefore just about the time Rabelais wrote this story about Panurge. Vesalius, with another student, used to go out to the burial ground, now called "Les Buttes Chaumont," near Paris, to get material. Here they were attacked and were nearly devoured by savage and hungry dogs.⁷

Infant's Teeth Called Treasures.—When Panurge asked Friar John if he should get married, the good priest told him he should, and indicated that it was no use for him to reserve himself, as the end of the world was fast approaching. He therefore urged him to seek out a wife, publish the banns, and purchase a bed. As an assurance that the day of judgment was near at hand he said that Antichrist, one of the chief personages preceding the great event, was already born, but as yet did no more than scratch his nurse and his governesses, and his treasures did not yet show, because he was still very small.⁸

Pliny, from whom Rabelais got so many references, both true and false, in natural history, speaks of the thesauri maxillarum, the treasures of the jaws, and any physician who has much to do with children knows what a great event in the family the first tooth or treasure is, and in fact each succeeding milk tooth. There is even an old legend, referred to by Shakespeare, that sometimes children are born with teeth.⁹

How Gargantua Cleaned His Teeth on a Pig's Foot.—Before arising from the table, Gargantua mumbled a few words of grace, washed his hands in cool wine, cleaned his teeth on a pig's foot, and conversed cheerfully with his comrades.¹⁰ It is usually translated that "he picked his teeth with a pig's foot." This I think incorrect. One of the most Rabelaisian men I ever knew used often to say that the best way to clean the teeth was to exercise them on a beefsteak. And Rabelais himself speaks of not having a crumb of bread wherewith to scour his grinders, and is so translated by W. F. Smith.¹¹

That exercise of the teeth, even if it does not clean them, tends to keep them in good condition,

is an old observation. Mercurial gingivitis, for example, appears more readily on the side not used in chewing, and inactivity of the teeth favors the formation of tartar, and predisposes to gingivitis, and so to the loss of the teeth.

How Agreeable to the Teeth Is the Tender Beef, Boiled Long and Slowly in the Soup!—Rabelais was a monk from his early youth until his death, and his remarks on cloistral life are very entertaining. They were remarks on the world in which he lived, and he was very much alive, and his genius lay in the way of setting down what he actually saw or experienced. For instance, the monks arose very early in the morning, and lit the fire under the great soup kettle in the community kitchen. The earlier they arose and the longer and slower the fire burnt under the pot, the softer and more tender the piece of beef would be. Rabelais tells us that it would become so soft and tender that it would melt in the mouth, and would not in the least wear down the teeth. Under such circumstances also the extracts would escape from the meat, and diffuse themselves in the soup, and lend it a delightful savor. These qualities in a soup would be particularly appreciated by the more elderly monks, whose palate, a little dulled by age, needed the stimulation of these savors, and whose teeth were not so good, and were apt to be sensitive both from caries and from gingivitis, at a time in the world's history when there were no dentists to set a delaying hand on Time's advance in this direction.

The monasterial masses were very long in winter, and the stone cloisters were chill. The monks arose long before the sun and clattered down the drafty passageways in their sandaled feet, with their hands clasping their arms in their ample sleeves. The chapels were as cold as the cloisters, and young Rabelais, with his vigorous body and youthful stomach, must have sung the psalm: *Vanum est vobis ante lucem surgere*. It is in vain to arise early in the morning, with a more than usual vigor, and with an apt appreciation of that steaming hot soup, which was awaiting him and his fellow monks in the refectory after mass.¹² Oh, la bonne soupe!

As another bit of monasterial color, Rabelais says that Friar John was a clerk to the very teeth in matter of breviary,¹³ indicating his punctiliousness in carrying out the ceremonies of the church.

The Feeling of the Teeth Being Whetted as a Symptom of Hunger.—When the good Pantagruel first saw Panurge, to whom he remained attached ever after, he found him in rags and starving. Panurge, immediately upon Pantagruel's expression of friendship, exposed to him the urgent necessity that was on him to feed. He said he had whetted teeth (*dents aiguës*, literally sharpened teeth), an empty belly, a parched throat, and a ravenous appetite, and that if he would only give him the opportunity to set to work, it would be a treat to see him at it, and urged him quickly to order the victuals. He ate soul satisfyingly, went to bed like a capon, and slept till dinner time of the following day. Then to show that one meal did not fill his emptiness, he made three steps and one jump from the bed to the table.¹⁴

Although modern physiologists do not seem to take cognizance of it, there is undoubtedly an eager

sensation in the teeth in hunger, and this Rabelais, so open to all such sensations, knew perfectly well. This eager feeling to get the teeth into something when anhungered is expressed by Shakespeare, also as a feeling of sharpness.¹⁵

Pulling the Teeth to Decrease the Appetite.—Pulling the teeth to decrease the appetite is only mentioned once by Rabelais. When Toucquedillon was threatened by a siege, he proposed to pull the teeth of his garrison, leaving to each soldier only three. He said that even with these they would lower their stock of food only too quickly. This, however, was likely only a picturesque way this eccentric general had of expressing himself, as a little farther on he says that when hunger reigns strength vanishes.¹⁶

Panurge's Account of Pantagruel's Teeth After He Had Journeyed a While in That Giant's Mouth.—Pantagruel put out his tongue, and Panurge jumped upon its back, and by diligently walking along, at length entered his mouth, where he said the teeth appeared as great white rocks like mountains, so huge that there were cis-dentine and trans-dentine peoples. At length Panurge climbed on the teeth, and found there playgrounds, tennis courts, galleries, and in fact all the amenities of life, so much so that he dwelt there for fully four months. After this he journeyed along to the back teeth, where he was more easily able to step down to the gums, and so attain the fold or valley between the lower gums and the cheek, in his journey toward the lips. Here, however, in the parotid region (the side toward the ears, *vers la partie des oreilles*), he ran into a nest of brigands in a great forest. I suppose it is only natural that a lawless lot of microbes should dwell here, seeing that this region is so difficult to reach with the tooth brush. Finally Panurge gained his master's mouth, and slid down by his beard to his shoulder, and thence to the ground.¹⁷

Toothache, Its Cause and Treatment.—On another occasion Gargantua the father of Pantagruel, wishing to refresh his stomach, went out into the garden and, gathering up some lettuce, washed it in a fountain of cool running water, and proceeded to eat it. Unknown to him some friars had hidden in the lettuce leaves, and he put them into his mouth with the leaves. In walking around the inside of his mouth and over his teeth in the dark, the pilgrim's staff of one of the friars stumbled into a cavity, and, striking a twig of the mandibular nerve (the inferior maxillary branch of the fifth pair), gave rise to an exceeding sharp pain. After considerable trouble Gargantua succeeded in picking out the pilgrim, and at first he thought he was a snail, as he mistook the staff for a snail's horn.

In the Middle Ages the toothache was a widely prevalent and much feared malady, and its etiology was as fantastically considered as the instance given above, and its treatment was equally fantastic. Rabelais recommends placing a copy of "the Great and inestimable Chronicles of the enormous Giant Gargantua between two fine linen cloths very hot and sinapised, and to apply this over the part affected."¹⁸ This was a joke, but founded on a well-known and much-employed practice.

I myself remember, as a little fellow, having a severe toothache, and being bundled up and taken to

an old farmer in the neighborhood, who had the reputation of steaming the worms out of aching teeth with herbs. By the time I arrived my toothache was over, and instead of being steamed, a bottle of toothache cure, costing twenty-five cents, was purchased for me.

The Idol of the Gastrolaters.—The gastrolaters, or those whose belly was their god, literally belly worshipers, had for an image a statue of wood, ill carved and clumsily painted. Its eyes were bigger than its belly, and its head was bigger than the rest of its body. It had an ample pair of wide and frightful jaws, with a huge set of teeth above as well as below, which by the device of a little cord, concealed within the gilt stick on which the image was borne, were made to rattle dreadfully against one another.¹⁹ Here we have the eyes large to signify greediness—as children characterize a greedy companion by saying that his eyes are bigger than his stomach. The huge teeth signify a ravenous appetite.

The above image, borne in procession, was an institution in the city of Metz, where Rabelais was for a time an exile. In San Francisco we are accustomed to a similar ceremony of the Chinese bearing in procession their picturesque and horrifying dragon. Sometimes the Chinese form part of our American processions. Our part consists of ugly floats with miners' cabins and set pieces, each uglier and more commonplace than its neighbor; the Chinese part, on the contrary, is all color, spriteliness and fun.

The Molars and Masticators.—It was desired to give a warm reception to some objectionable officers of the law, who were serving papers on a debtor. These people could not be thrashed openly, so under the guise of a jolly, frolicsome ceremony at a wedding, and according to an old custom, gauntlets were drawn on, and they proceeded to break the bones of those officers of the law in a most scandalous fashion, and all under the guise of good fellowship. One of the victims had his upper jaw dislocated, so that it fell down over his chin, exposed his uvula and caused him a notable loss of his teeth, molars, masticators, and canines.²⁰ Our nomenclature of the teeth runs: incisors, canine, bicuspid, and molars—I do not know what distinction Rabelais drew between molars and masticators.

Loss of the Teeth Due to Contagious Disease.—Teeth are mentioned as having fallen out after wearing a mask made of leaves torn from an old book of the decretals. The decretals were compilations of papal decrees or laws, and the inference was that the sacrilege committed by making a mask of the leaves was punished by the teeth of the wearer falling out.²¹

Loosening of the Teeth in Mercurial Ptyalism.—Rabelais, also, in speaking of his doleful luetic and gouty patients, says that, after being well anointed and thoroughly greased, their faces shine like the metal plate on a meat safe, and their teeth rattle like the keys of an organ when played upon.²² This serves to indicate the extreme symptoms of mercurial ptyalism usually obtained in the treatment of syphilis in his day, and also the bad adjustment of the organ keys in an age not distinguished by its mechanical perfections.

The Use of the Teeth as a Surgical Instrument.

—In one situation, Rabelais mentions the use of the teeth as a kind of surgical instrument.²³ This is not original with him. Down to quite recent times ritualistic circumcision was performed with the teeth, the rabbi biting off the foreskin. Many cases of infant syphilis have been reported contracted from this practice.

In referring to the teeth, as to almost everything personal to the human being, Rabelais exhibits a realism and a vividness nowhere else encountered. Anatole France is the only author I am acquainted with who can make anything like such rich and striking use of medical facts for example.

Another interesting feature brought out in a study of the references to the teeth in Rabelais is the infrequent mention of them as weapons, so usual in our own literature, as "showing one's teeth," "fighting tooth and nail," and the employment of the word "cynical," indicating a slight uplift of the right upper lip to expose the canine or dog tooth in fighting. Snarling and biting was contrary to the light-hearted, Gallic humor of Rabelais. Its insistent recurrence in our literature harks back to a time before the Marquis of Queensbury reigned, and when the teeth were well recognized and frequently employed weapons of offense, as they naturally should be in all carnivorous animals.

Four Errors in Diagnosis.—Roqueta gives the following: Swallowed blood from epistaxis mistaken for hematemesis from swallowing raw alcohol by error; urethral obstruction by a huge mass of feces in the rectum mistaken for ordinary urinary retention; fibroma of the uterus of many years standing with metrorrhagia had been mistaken for bleeding from the cervix; radiograph of thorax which indicated a thickened area of tuberculous pleurisy had long been interpreted as an enlarged lymph-node plaque.—*Revista Médica de Sevilla.*

PRIMITIVE TREATMENT OF DISEASE.

BY J. BARKLEY PERCIVAL, M.D.,

PARAMARIBO, DUTCH GUIANA.

PRIMITIVE man suffered much from wounds, bites and stings of carnivorous animals, snakes, and insects. Necessity drove him to search for remedies with the result that he found many useful dressings.

He saw animals licking their wounds, and no doubt found that it assisted in the cure. Children who are nearer to the primordial stage, still put a cut finger in their mouths with good results. Sucking a snake bite as a remedy is known all over the world and still used, although rarely beneficial. Beasts also bite at their feet when they suffer from thorns, and use teeth and paws to catch parasites. Monkeys are particularly noted for picking their fur and eating what they capture. Primitive man had similar feelings to those of the other animals, and no doubt in the same way.

We may go back to a time before the uses of fire had been discovered. The man went out to hunt and was mauled by a beast either with teeth or claws. If the wound was small he licked it; if large he would go to the nearest stream and wash it with cold water. In some cases this would fail and the bleeding be continued. He pressed the edges together with his fingers and found that the bleeding stopped so long as the pressure continued. But he could not stop here all day with perhaps both hands employed; he must go home. He might be able to walk, or on the other hand be faint from loss of blood. His hands were weary through holding them in a cramped position. Our children run to their mothers and get their cuts tied up with clean rags. There were, however, leaves of trees, and he tied them tightly with a bush rope, so as to be able to carry his weapons and crawl home. He could not move without a weapon, even were it only a club, and therefore must have the wound secure without interfering with the use of his hands.

Experience led to the discovery that certain leaves stopped bleeding. I find that the silver fern is still used, and also a tree fern. The first has white and powdery and the other brown line-like scales. Both can be easily obtained in the forests of tropical America. This is very important, for the remedy must be at hand in an emergency. We might know of a better remedy, but if we have to go miles to fetch it, we must put up with something inferior.

One of the most widespread of our plants here in Guiana, South America, is the moka-moka. It is everywhere in the shallows of our creeks and rivers and is, therefore, more easily available than many other remedies. It is one of the best applications to wounds, and may be applied raw or after wilting over the fire. The usual dressing is a slice of the growing stem, but it is also applied as parings or shavings. Wonderful cures have been reported where serious wounds have been dressed with the warm slices, and I have every reason to believe them true.

An early voyager spoke very kindly of the prickly pear, a plant well known to the creoles or natives of these countries, and used as a dressing for almost everything. He said that it was used for

broken and dislocated limbs; after warming over the fire, the branch was split open and the succulent part applied as a kind of splint, with such good results that Europeans had their limbs dressed by the Indians. In the islands of the Caribbean Sea the prickly pear was common, but we can hardly say it is a native of Guiana. However, the moka-moka was used here in the same way, and when split open and wilted could be applied for similar purposes.

A broken limb was an accident from which few could recover; if the primitive man were helpless he might be considered as dead. A rather pathetic story is told by an African traveler. He went out hunting with the chief, and noticed one of the men with a broken back actively running about on all fours. Remarking that the man was so very active, he praised him, on which the chief quietly hinted that had not this been the case, and had the man been helpless, he would have died long before. There were no places for incurables in primordial society.

Men who lived under natural conditions suffered less from wounds because they generally healed, like those of animals, without festering. If one leg is broken, the dog runs on three, but the man of the forest is helpless, and dies. We never find crutches or peg-legs among wild tribes. Common dressings for wounds and ulcers are barks of trees containing tannin. They are scraped into a sort of tow, thus providing lint and lotion in one. They are certainly useful, and may be compared to gall ointment or tannin preparations. These are used without cooking in any way, but there are also decoctions of such barks used as washes. The wounds are always tied up with leaves and thus protected, but I do not find that cotton was ever used as lint.

For swellings there are many kinds of leaves employed; some are counterirritants like dumb-cane, others soothing like tobacco, and a host that appear to be inert, such as cophalic leaf.

Bleeding is recorded as having been practised by the West Indians, and I have seen an Indian boy here whose ankle was sprained by his stumbling when carrying a load. His father washed the ankle with water and then pricked it with the point of a knife until it bled; in an hour he took up his load and marched on.

Snake bites were hardly considered curable, but there was a preventive in the shape of the Laburia plant, which was used as a beena or charm to prevent the attacks of the snake. Whether the form of inoculation against snake bites now used by some natives here was originally got from the Indians is doubtful, but we may say that the process of inoculation is primitive in the case of beenas.

As may be supposed, the jiggers were always a pest, and the Indians must have learned to extract them with a palm needle or pointed stick long before they came in contact with Europeans. The simple dressing with wood or tobacco ashes was also well known. But there have always been lazy people, and we may suppose they were not unknown here, or the mode of treating bad cases of jigger penetration could not have been discovered. Strangers often suffered much from these fleas; the following extract from Leigh's voyage to Guiana (1604) brings the matter home to us:

"We were mighty vexed with a kind of worme, which at first was like a flea, and would creepe into

the feet especially, and under the nuyles, and would exceedingly torment us, the time it was in, and more in the pulling out with a pinne or needle, if they were but few. But one of our men having his feete overgrowne with them, for want of hose and shoes was fain to submit himself to the Indians' care, who trying one of his legges first with his feete upward poured hot melted wax, which is blacke, upon it, and letting it lye upon it till it was thoroughly cold, they forcibly pulled it off and therewithall the wormes came out sticking in the same, seven or eight hundred in number."

There is a fly pest known as the mosquito worm which can be extracted after covering its tiny breathing pore with a bit of wax, pitch, or plaster. Only a very lazy person need suffer from these, but they can, if neglected, give much trouble. The same may be said of bush ticks, which can be dislodged after dropping oil upon them or by bringing a fire-stick close enough to warm their backs.

Mosquitos are repelled somewhat by crab oil, as are also caburi flies and sand flies, but no real protective measures have ever been discovered. The smoke of green leaves was no doubt an old preventive, as was also the round hut of the savannah with its closed sides. But even with the smother in a savannah, the Indians have to migrate during the height of the mosquito season.

Indians have always suffered from sore eyes, which they attribute to a tiny fly sucking the edges of the eyelids. Quite a large number of herbs are used in the treatment, some of which are succulent, their juices being squeezed into the eyes. Among them are wallaha leaves, congo cane blossom, and the tree of life. Bancroft said the Indians tied a leaf of moka-moka over the eyelids, with the result that a plentiful discharge from the glands took place, and a reduction of the inflammation. He also said that Europeans followed their example with good results. No means of protection from these flies has been discovered, notwithstanding the drawbacks to a huntsman when anything affects his sight. It may be understood that this is a somewhat heroic remedy, for the same leaves were once used by malingering slaves to cause swellings in the legs so that they might lie down for a day or two. When the reader sees moka-moka again he may perhaps recognize in it a cure-all of great potency, possibly rivaling the advertised pain killers. For external use it appears safe, but it is certainly poisonous.

Ground itch is one of the troubles due to insects, and is very common in Guiana. Several cures are mentioned, but all have not been effectual in curing this malady.

In concluding this article, I must call attention to the fact that no attempt has been made to give a full list of the remedies; this may be done in the near future. The point to which I draw attention is the fact that the native Indian has learned by long experience to treat the results of his accidents and to repel his pests. Like the European he has failed to find specifics. What he has done is to recognize that certain plants growing near at hand are useful and also that they must be applied in certain ways.

There is nothing here to take the place of anti-septic dressings, and not a single remedy that can be introduced into our hospitals. Nevertheless,

they are good in their way and useful in places where there are no medical men. The most we can say is that they are fair substitutes.

There is one great drawback to the adoption of bush "medicines." They cannot be preserved in any way to retain their properties. Take moka-moka, for example; it is everywhere except in the cities. We can have a piece of sticking plaster in the house or get it in a few minutes, but it might take hours for a person to leave the city to find a piece of moka-moka.

Some may object to my statement that moka-moka cannot be preserved in a way to be available. The answer is connected with our knowledge of the natural orders of plants. The order to which this belongs is Arvideae, which includes such plants as tania and scratch odoes. All have acrid secretions which are dangerous, but so far as is known none retains its properties after cooking or drying. The dumb-cane is probably the most virulent of the order, but even this loses its properties when dried. Other plants that are virulent poisons when fresh become edible when cooked. It is hardly necessary to mention cassava in this connection, but it is a good example.

Medicolegal Notes.

Expert Opinion as to Permanency of Injury.—In an action for injury resulting from the negligent operation of an elevator it was held that the opinion of an expert physician as to the permanence of the injury, based upon sufficient evidence of the facts, was competent and relevant to show that the injury was permanent. The court quoted *Parrish v. Railroad Co.*, 146 N. C. 125, where it was said: "It was necessarily assumed by the very form of the question that the jury might find that whatever injury the plaintiff had suffered was directly caused by the fall, and the witness was called upon to state what the physical conditions produced by the fall indicated to his trained and experienced mind as a medical practitioner. We think the evidence comes strictly within the rule admitting expert testimony, or that which is given by a witness having special or peculiar knowledge and skill in the particular calling to which the inquiry relates; and the competency of the question, as predicated on the hypothetical facts stated, is sustained by the best-considered authorities."—*Taylor v. Tallassee Power Co.*, North Carolina Supreme Court, 94 S. E. 432.

Validity and Infringement of X-Ray Machine Patent.—The Circuit Court of Appeals, Third Circuit, holds that the Snook patent, No. 954,056, for an x-ray machine, covers an invention of a novel character and a high order of merit, in which, by discarding the use of induction coils and using an alternating current, the inventor greatly increased the intensity of the rays and prevented inverse discharge through the tube, adding greatly to the utility of the machine. Prior to this patent the x-ray machine in common use was called an induction machine, and its capacity was about 8. Snook, who was a trained electrical engineer and manufacturer of such machines, after repeated efforts to increase current intensity and eliminate inverse current tendency in the field of induction coils and high-peak contacts, abandoned it and turned to two other factors, namely, the use of substantially the whole of the sinusoidal curve as a contact element; and, second, the employment of an alternating current by a suitable switch or rectifier connection. The testimony of physicians satisfied the court that while the best results of former machines, expressed in milliamperes, was about 8, with the Snook apparatus they were able to obtain 120; in other words, virtually 15 times as great light-exciting power. This ray intensity brought about higher penetrating power, and therefore sharper and more definite photographic reproduction. The patent was also held infringed.—*Stetson Hospital v. Snook-Roentgen Mfg. Co.*, 245 Fed. 654.

Military Medicine.

The Medical Aspects of Aeroplane Accidents.—H. Graeme Anderson, Temporary Surgeon, R.N., attached Royal Naval Air Service, treats of the causes of aeroplane accidents and the method of emergency treatment of the injured cases in an article in the *Journal of Royal Medical Service*, from which an abstract was published in the *British Medical Journal*, January 191, 1918.

With the slow, sure method of teaching fliers before the war accidents were comparatively few; but as the war advanced and the importance of aviation was recognized more pilots were needed and the methods of teaching had to be accelerated, and pupils were sent off to do their first solo flights after a few hours' dual-control instruction. This naturally has increased the number of accidents, together with aerial duels or anti-aircraft fire from the ground.

Anderson classifies accidents at his station covering a period of six months, which he calls the "V" series. In this series 4,000 hours' flying were done consisting of 9,000 flights, in which 58 aeroplanes were wrecked or crashed. The suggested definition of a crash is an aeroplane so damaged in a flying accident that it has to be deleted or sent into the workshops for repair or rebuilding. This is in contradistinction to the effects of a bad landing or get-off where the ensuing damage is small and can be repaired by the flight mechanics. Fifty-eight crashes in 9,000 flights represents one crash in every 155 flights. In these 58 crashes 16 airmen were injured, which is equivalent to 28 injuries in every 100 crashes, or one pupil injured in every 560 flights.

These figures show that school flying is fairly safe and compares favorably with other high velocity forms of transit. There was a greater frequency of crashes on the first and second solos, then a diminution from the third to the sixth inclusive, and a rapid rise again in the seventh, indicating a too-sureness on the part of the pupil with overconfidence and carelessness exhibited.

The causes of aeroplane accidents given are: (1) Defect in the aeroplane; (2) error in judgment in flying; (3) "loss of head"; (4) brain fatigue or lethargy; (5) fear; (6) physical illness; (7) unavoidable causes. In this total of 58 cases but one crash came through a defect in the aeroplane, while error of judgment in flying caused 42 of the crashes. Here, the commonest error is made on landing, when the pupil misjudges his distance from the ground, and either "flattens out" too soon and "pancakes," with a possible crash, depending on the height, or else "flattens out" too late, and strikes the ground at a varying angle, usually overturning and wrecking the machine.

It is difficult to estimate and account for these errors of judgment. In some cases Anderson attributes it to underinstruction, while in others even after prolonged instruction the pupil may still misjudge distance. This may be due to the flier's standard of vision being below normal; or, on the other hand, the vision may be normal and the balancing power good, but the reaction time may be delayed. It is upon this visual reaction

time that the aviator is so dependent, and which normally takes nineteen one-hundredths or twenty one-hundredths of a second. Fatigue, drugs, and excesses may cause it in some individuals, while in others who may be physically fit it may be normally slower. Hence the selection of candidates for aviation should be made with reference to their visual reaction times. The French medical authorities on aviation reject candidates whose reaction times are found to be of the delayed type.

Among the other causes for crashes, loss of head occurs fairly frequently—seven in the series given. Under the sudden strain of emergency the power to reason and act synchronously may momentarily lapse, resulting in this condition. In flying fractions of a second count enormously and may mean all the difference between danger and safety. After loss of head there is seldom time to correct the error made. Brain fatigue caused four of the accidents out of the 58, and is due to repeated stimuli received in rapid succession by the brain of the aviator in his flight. He feels alone; a succession of errors occur in the air; he feels he cannot manage to control the aeroplane; fear does not seize him, but the enormity of the whole thing appals him; he feels helpless, and a state of brain fatigue occurs in which he, in a stupor, awaits events and takes little part in the aeroplane's control. In brain fatigue the pupil fails to flatten out and the aeroplane strikes the ground at its gliding angle and becomes wrecked. Upon questioning these cases it is found that there is very little recollection of what happened during the flight; memory seems to be partially stunned. As a rule the pupil soon gives up flying though he has not been injured. He is not of the temperament suitable for flying. Physical illness occurs occasionally, though rarely. Anderson cites a case of an epileptic who was seized with an attack while flying and who was dismissed from the work.

Strangely, fear does not play an important part as a casual agent in these crashes. The mind is too much occupied with the various details of the mechanism and the running of the machine to allow thought for personal considerations. Many confess to a sense of danger lurking somewhere at the back of the head, but say that it rarely ever asserts itself.

Anderson offers a scheme for first aid at an air station. The sick-bay or dressing station should be in full view of the aerodrome with a lookout man supplied with field glasses always on duty during flying hours. Telephone connection should always be possible with this man, and immediately a crash or false landing is made he should telephone to the sick-bay station notifying the steward of the location of the accident. A wheeled hand stretcher on which is carried a first aid dressing bag and an emergency tool kit must always be on hand. The steward on being notified of the accident dispatches the ambulance, which stands always in readiness by the sick-bay, to the scene of the accident. Two sick berth attendants go with the ambulance, and with them is a bag containing morphine solution and two Willey's hypodermic syringes, a bottle of chloroform and a face

mask, brandy, a bottle of sterilized water, six first-aid field dressings and slings, picric acid dressings, a tourniquet, cloth cutting scissors, and a knife. These articles can easily be packed into a small bag 10 in. by 8 in. by 3 in.

The surgeon on duty is on the aerodrome during flying hours, and proceeds to the scene of action by car or foot, or if any distance is to be covered an aeroplane is used. Flying pupils should not be allowed to come near or to help, except in exceptional circumstances. Often the crash is so severe that the wreckage has to be cut away from the injured aviator. Under no conditions must he be dragged from under the debris, but gently lifted from under when the wrecked plane cannot be moved. The safety belt is cut and the pilot gently slid out of the seat. The aeroplane seat cushion is placed under the injured pilot's head, while his body rests on a flying coat spread out on the ground. A rapid examination determines the extent of the injuries. If he is conscious and in much pain morphine should be injected and he should be quickly conveyed to the dressing station, where clothes are cut away and injuries examined, and treated accordingly. If unconscious, some cutting away of clothing can be done on the field, injuries examined, and perhaps a dislocation reduced or a fracture accurately diagnosed during the unconscious period. The pilot's leather clothing protects him from fire for a length of time, but the face and lower limbs rarely escape, and when the pain is very severe, and also when other injuries are sustained, chloroform should be administered on the field, and this is kept up on the way back to the dressing station. It aids the work before the morphine begins to act.

The injuries sustained are those incident to all high-velocity accidents, but are more severe, due to the enormous speed sustained by the air crafts. Injuries due to crushing, where some part of the body gets crushed between parts of the wrecked aeroplane; injuries due to collision with the ground, as when the pilot is thrown out, falling on his head; injuries due to impact with different parts of the aeroplane, as when the head is jerked forward violently and strikes the edge of the nacelle on the aeroplane's impact with the ground; injuries from fire; drowning and immersion effects in seaplane work, and suspension effects as when the pilot is suspended head downward in an overturned aeroplane and is unable to loosen his safety belt. This impact with the belt often causes abdominal injury. The injuries sustained depend much on the type of aeroplane and the cause and type of accident. The present day aeroplane is much stronger in construction and more powerfully built than in earlier days, thus providing for a greater margin of error on the pupil's part. On the other hand, in a nose dive in this type of machine the engine, being behind, is likely to crush the pilot severely, and usually kills him.

As means of prevention of accidents, Anderson approves certain of the safety belts and safety helmets, especially in the school work. An ideal safety helmet should be light and take its support from the shoulders. Goggles are a necessity to ward off conjunctivitis.

Scurvy in the Army.—Epidemic scurvy may be overlooked, for while we are aware of the individual manifestation, which may in part be commonplace, the total episode escapes observation until some time has elapsed. Such an epidemic has been reported in the *Paris Médical* by Harvier, physician in charge of a medical sector. The first cases to which attention was called were set down as rheumatoid purpura. Then a patient was seen who presented extreme anemia with broad ecchymoses on the thighs, edema of the legs, and fungous, ulcerating gums. An organized inspection of troops brought to light no less than 184 cases which, under one diagnosis or another, had been invalidated temporarily. The diagnosis included edema, rheumatism, and various traumatisms. Closely regarded, every patient was found to have scorbutus. The search was now extended to the nominally sound individual, and, in one group of 285 men, 20 per cent. were found to have bleeding gums. At the completion of the work over 800 men, or 95 per cent. of all suspects, were pronounced scorbutic in some degree. The total number to require internment was 110. The lesions comprised every form of hemorrhage—including peculiar small hematomata in the skin, edema, and scorbutic gingivitis. Prompt recovery followed the use of salad vegetables and lemons (half a lemon daily per man) with aspirine or sodium salicylate for the pains. Prevention was guaranteed by the use of a piece of lemon daily with vegetables (cabbage, onions, carrots, and salads).

Sanitary Work in Areas Around Military Camps. The United States Public Health Service is carrying on an active campaign along sanitary lines in the areas adjacent to 28 military camps and cantonments throughout the country. Complete sanitary organizations, composed of personnel supplied by the Public Health Service, the American Red Cross, and the State and local health authorities, are at work in these areas for the purpose of preventing the spread of disease from the civilian population to the military forces and to protect the civilian population from communicable diseases where they have occurred among troops. The sanitary organizations include physicians, sanitary inspectors, sanitary engineers, public health nurses, attendants, and laborers. The measures undertaken include the medical inspection of school children, inspection of all establishments handling food supplies, inspection of barber shops, purification of unsafe or questionable water supplies, installation of sanitary methods for the disposal of waste, and drainage or filling in of mosquito-breeding places. It is stated that there are engaged in this work about 440 employees of the Public Health Service. The Red Cross has furnished 177 scientific and technical assistants, nurses and inspectors, and over 200 laborers to assist in the campaign.

Additional Hospital Accommodations for Wounded.—The Surgeon General has recommended that the general Government hospitals shall provide 60,000 additional beds before the winter of 1918-19 to care for wounded soldiers and sailors. Under the Surgeon General's plan each general hospital, when completed, would have between 1,000 and 1,500 beds. Recommendations will also be made for the establishment of a general hospital organ-

ized as a colony for the treatment of men suffering from epilepsy.

Government Tuberculosis Hospitals.—A large tract of land has been acquired by the Government adjoining the New York City Department of Health's municipal tuberculosis sanatorium at Otisville, N. Y. The Government intends to erect a hospital to house 800 soldiers suffering from tuberculosis. The New York City Health Department has placed at the disposal of the Government its pavilions on North Brother's Island. It is expected that the new hospital at Otisville will be completed within four months. Other homes for tuberculous soldiers are to be established at New Haven, Conn., at Whipple Barracks, Prescott, Ariz., Asheville, N. C., and Denver, Col. It is understood that they will cost about \$550,000 each.

Addition to Columbia War Hospital Opened.—The new section of the War Hospital of Columbia University was opened for service on February 15. Eighteen new wards have been added, practically doubling the capacity of the hospital, so that some 1,000 patients can now be cared for at the same time. The hospital is intended to care exclusively for those brought back from the Expeditionary Forces in France, although there are at present 200 patients from training camps and 200 from the army in France being cared for. Colonel Edward R. Schreiner, chief surgeon, and commander of the hospital, has been ordered to the Government Hospital at Fort Riley, and has been succeeded by Major W. H. Bishop.

Investigation of Sanitary Conditions at Camp Greene Ordered.—In a report to the Secretary of War, recently made public, Surgeon General Gorgas demands that the unsanitary conditions at Camp Greene, near Charlotte, N. C., be corrected. Following a conference, Secretary Baker has ordered an investigation of the camp. Surgeon General Gorgas has ordered the installation of a new sewer system, and that additional tentage be furnished so that the men can be quartered on the basis of five men to a tent, instead of eight, as is now the case. At the conference the statement was made that the unsanitary conditions found at Camp Greene were not local, but were general throughout the camps in the South. The Surgeon General expects to visit all the camp hospitals in the South and familiarize himself with the conditions there present before returning to Washington.

Doctors Called, to Be Massacred.—A despatch from Stockholm states that as a climax to the massacre of Kerava the Red Guards wired to Helsingfors for surgeons and ambulances. Five surgeons left immediately, on an errand of mercy as they supposed. On their arrival they were murdered by the Red Guards.

American Sanitary Unit Wins Honors.—Surgeon General Gorgas has received word from Col. J. R. Kean, chief of the ambulance service of the American Expeditionary Force, a message stating that the American Sanitary Unit 646, serving with the French forces, has been twice cited in French orders, and has thereby won the award of the Croix de Guerre.

Major Grayson M. P. Murphy, former Red Cross Commissioner to Europe, has reported to General Pershing for duty with the expeditionary forces.

Death in the Service.—Dr. Henry E. Hungerford of Waterbury, Conn., a graduate of Yale University Medical Department, in 1898, died of pneumonia at Fort Oglethorpe, Ga., on February 1, aged 45 years. Dr. Hungerford was commissioned first lieutenant in the Medical Reserve Corps, U. S. Army, and was assigned to duty at Fort Oglethorpe on January 17.

Cerebrospinal Meningitis Spread by Carriers.—Dr. J. Lewis Amster, Commissioner of Health of New York City, announces that the city's research laboratories have been assisting the Government in determining the number of human meningitis carriers in the various camps. It is announced that a new method of making the examinations has been instituted whereby a large number of specimens may be examined in a short time. Within a few days 123 soldiers were examined by the Health Department Laboratories and 31 carriers found.

Campaign to Secure College Girls as Nurses.—Under the auspices of the Red Cross and the Council of National Defense a campaign has been launched to recruit 5,000 college women for the training camp for nurses to be held at Vassar College next summer. The training-camp college will open June 24, under the auspices of the Red Cross and the Council of National Defense. College women who have graduated within the last ten years from universities and colleges recognized by the Association of Collegiate Alumnae may take the course, which consists of three months' intensive training.

Mount Sinai's Contribution to the War.—Mount Sinai Hospital, New York, announces that it has 75 physicians commissioned in the Medical Reserve Corps. In addition, more than 40 members of the Mount Sinai Alumni Association have been commissioned and assigned to active duty. Several of the trustees are also serving in various branches of the service. Sixty-five of the nurses, including the associate superintendent and the night superintendent of the nurses' training school, are in Base Hospital Unit No. 3, now in foreign service.

The Committee on Hospitals of the General Medical Board of the Council of National Defense has been reorganized with the following membership: Drs. S. S. Goldwater, chairman, New York City; Winford Smith, Baltimore; Joseph Marshall Flint, New Haven, Conn.; Shepherd I. Franz, Washington, D. C.; Edward Martin, Philadelphia; F. F. Simpson, Washington, D. C.; Robert E. Noble, Colonel M. C., U. S. A.; and Frederick A. Washburn, Boston, Mass.

Farewell Dinner to Overseas Hospital Staff.—A farewell dinner was given to the staff of the Women's Overseas Hospital, which will sail for France this week, at the Cosmopolitan Club on the evening of February 11. This unit is supported by the National American Woman Suffrage Association.

An American Surgeon Wanted in Serbia.—The Franco-Serbian Field Hospital of America is in need of an experienced surgeon for their hospital, which is located near Bonitsa, just behind the Serbian lines. Dr. Ryan, who gained distinction by his work as head of the American Hospital at Belgrade, is in charge of this hospital. Anyone willing and able to undertake the work may apply at the office of the organization, 25 West Thirtieth Street, New York City.

INDUSTRIAL EFFICIENCY.

ONE effect of the war has been the stupendous impetus which it has given to manufacturing efficiency, especially in all manufacturing related to the conduct of war. Science has been called upon to further the ends of the warring nations in every direction. Not only is this the case at the front, where scientific methods of every kind for destroying life are employed, but in the hospitals, the camps, the factories and homes. Scientific living is being taught and practised, as it is recognized that in food conservation and transport lie the crux of the problem of how to win the war.

Dr. Frederic S. Lee, writing on industrial efficiency in *Public Health Reports* for January 11, 1918, draws attention to the fact that industry has never been backward in accepting and utilizing scientific discoveries. According to the writer, the phenomenal industrial advances of recent decades have been due chiefly to the achievements of two sciences—mechanical engineering, which has invented and developed automatic machinery, and chemistry, which has discovered new chemical substances and new chemical processes. However, although all these means have greatly reduced the need for manual labor, the human being has not been eliminated. The mode of work has changed, but men and women are as necessary as ever to the performance of industrial work, and the problem nowadays is how to obtain the greatest efficiency from the human material. Sanitation has done much in bettering the conditions of the workman and workwoman and thereby has increased their industrial value. Industrial medicine has done something in the same direction, but the problem has not been really solved, and Lee is of the opinion that in recent years it has become clearer that a good deal of light can be derived from physiological science and that a new application of physiological principles, an industrial physiology, if one desires a specific title, has been gradually appearing.

From this standpoint, it is the human machine that is to be considered, the most delicate and intricate of all the machines employed in industry. If this machine is not in good working order, output diminishes, work is badly done, accidents occur, and efficiency is generally retarded. Nothing is so apt

to impede efficiency as fatigue, and consequently one of the main objects is to keep down fatigue as much as is possible.

British observers before and especially since the beginning of the war have investigated this subject, and in America the Committee on Industrial Fatigue of the Advisory Commission of the Council of National Defense, associated with the Public Health Service, has pursued investigations along similar lines.

The most obvious problem perhaps of industrial efficiency is that of the duration of daily and weekly labor. When the war had been in progress for some little time, the activity in the munition factories was at a feverish height in Great Britain and the hours of labor were greatly increased. Overtime and Sunday labor were resorted to frequently. It was soon found, however, that the burning of the candle at both ends did not pay in the long run. Excessive fatigue was produced, and both quantity and quality of work were greatly diminished. It was discovered that longer hours do not necessarily imply a larger output. While a workman can obviously accomplish more in two hours than he can in one hour, it does not follow that he can do more in 15 hours than in 12, or more in 12 than in 10, or even more in 10 than in 8 hours. In the case of youths, girls, and women it was shown that more work of better quality could be accomplished when the hours were limited to the capacity of the workers. For example, Vernon of the British Committee accumulated statistical evidence of the beneficial results of a reduction of the hours of labor. The following instances will illustrate the point: With a group of 80 to 100 women turning aluminum fuse bodies the reduction of the weekly hours of actual work from 66.2 to 45.6, a saving of more than 20 hours, increased the gross production by 9 per cent. When the actual working hours of 56 men engaged in the very heavy labor of sizing fuse bodies were reduced from 58.2 to 51.2, the gross output was increased by 21 per cent. The American Committee discovered a strikingly suggestive fact in the night work of one of our large munition factories, the duration of the night shift being 12 hours. After 5 A. M. the curve of output showed a rapid decline, and during the last 40 minutes there was very little or absolutely no production.

Thus, as Lee points out, industrial physiology tells us, in the interest of a large output, not only to keep the hours of labor down to what experience has shown to be a reasonable limit, but to choose the limit in accordance with the fatiguing effects of the different specific occupations. The work must be adapted to each one's capacity, or rather the average capacity of workers must be ascertained and must not be exceeded. Also, each worker and each task possesses a specific standard of strength, and industrial physiology indicates in what task each worker will probably prove most efficient.

The scope of industrial physiology is wide, and by the intelligent use of it, industrial output and efficiency can be greatly augmented. In these days

it is essential that both efficiency and output should be at their height and therefore it follows that this is the appropriate time to place this work upon a scientific basis and in accord with the principles of industrial physiology.

SOME MEDICOLEGAL ASPECTS OF THE MANIC-DEPRESSIVE PSYCHOSIS.

WITHOUT going too deeply into the legal conception of insanity—and insanity is, after all, a legal, not a medical concept—it is, perhaps, enough to say that a crazy man, in the eyes of some judges, most lawyers, and practically all jurymen, is a man who sees and hears imaginary things, is excited, tears up things, assaults people, goes nude, and does other things calculated to attract attention. By a great effort of the imagination these people may conceive of a man suffering from fixed delusional ideas, persecution, grandeur, and what not, which influences his conduct to the extent that he takes elaborate precautionary measures, or proclaims himself a great personage.

But a disorder whose episodes are separated by periods of lucidity when the subject appears normal to the layman, a disorder which is sometimes manifested by episodes in which the excitement or the depression is so slight as not to be suspected of being pathological by his friends; and finally a disorder the two phases of which are so exactly opposite, and which exhibits frequently the so-called "mixed states" where depression is associated with flight of ideas and increased psychomotor activity, where exaltation is associated with difficulty of thinking and retardation, and so on *ad infinitum*, such a disorder presents many peculiar problems in its legal aspects. For example, in the prodromal period of a manic excitement, or a depression, the patient may take a drink now and then, in the former case merely because he is restless and exalted, "feels good," and in the latter case because he "feels blue," and has a vague idea of seeking artificial cheer. Suppose then that he is seen several times in an excited condition, the smell of liquor is noticed on his breath, and then he is arrested for some crime. Naturally, witnesses appear who testify that the defendant never acted peculiarly except when he had been drinking, that he was frequently drunk, and so on.

Furthermore, let us suppose that a patient has been in an "interval" for several years; on a certain day it so happens that he is not seen for several hours by any one who knows him; something occurs to precipitate an excitement—and a manic excitement may come on very suddenly, explosively, in fact; during this excitement he commits an overt act and comes within the purview of the law; and immediately following this act he is semi-stuporous for a time, and gradually emerges from that state into an interval during which he is put on trial. Now, it is difficult, almost impossible, to convince a jury that this man who appears before them quiet and composed, about whom wit-

nesses may be found in plenty to testify that he has always seemed sane to them, that they saw him the day before the crime, for example, and he seemed perfectly all right. An effort to show that the prisoner is of a manic-depressive make-up, that he had a mild attack some years since (about which many witnesses will testify that it was due to drink), that a sudden attack was precipitated by an emotional shock of some kind, during which attack he committed the crime, will be regarded with great suspicion by the public. These are but instances of the phases of the problem presented by the manic-depressive. In many other ways the manic-depressive may come into conflict with the law, but the essence of the problem remains the same, and depends on three chief things—the lucid interval, the existence of the slight episodes of excitement and depression, and the alcoholic features.

The average attorney will find it difficult to understand, moreover, how a man may go from normality to excitement in the twinkling of an eye, so to speak; also that such excitement may vary very greatly from day to day, or even from hour to hour, so that such a subject may be seen by witnesses one hour who discern nothing abnormal in his conduct, and others see him the next hour and describe him as a "raving maniac."

SUPPRESSION OF ABORTION.

IN connection with the subjects of low natality and repopulation, European governments naturally pay much attention to the deliberate or facultative abortion because under such circumstances gestation is actually under way, the woman and her husband are physiologically competent, and oftentimes the woman has conceived willingly, the motivation for interruption of pregnancy having been a subsequent development—for example, the pregnant woman has suddenly lost her husband so that the unborn child would be deprived of his protection.

It is evident that propaganda concerning abortion involves the careful study of statistics and in the *Journal de médecine et de chirurgie pratiques* for September 25 is a report made upon this subject before the Paris Medicolegal Society by Tissier, in which it appears that before the war the number of births in Paris per week varied from 1,000 to 1,200, equal to 55,000 per annum. Of this number of mothers from two-thirds to three-fourths required some form of State aid (almost 40,000). There is official cognizance of at least 20,000 annual abortions, so that the number of pregnancies is about 75,000 yearly. But of thousands of silent abortions there is no official record, because the women escaped accident, and Tissier estimates that there is official cognizance of but one abortion out of two or three or somewhere between 50,000 and 60,000 per annum. In other words for every birth an abortion.

These totals do not help much, for we have no means of knowing how many abortions are provoked. Lepage guesses 80 per cent., while others

place the figure much lower. But 25,000 to 30,000 seems a conservative estimate, a frightful picture—for in addition to the lost children hundreds of women die of sepsis and hundreds more become, so to speak, cripples incapable not only of further procreation but of self-support.

The correction of this state of affairs by law with the numerous "musts" and "shoulds" inevitable in an antiabortion propaganda has a more or less hopeless promise, largely because such recommendations cannot be promptly carried out on a small scale to show whether progress can be made. All know that programs of reform are often followed by an aggravation rather than improvement of evils when not backed by public opinion. In February, 1913, recommendations were made by the society to the French Senate and were adopted in the first reading. Last July further recommendations were made to the Senate by the same body for the carrying out of the original repressive measures. These had to do with reporting all stillbirths by parents, immunity to any woman who denounces the person who procured the abortion upon her, privilege of private testimony by medical men in regard to criminal abortion, and the right of direct citation, in connection with criminal abortion, to all societies actively interested in bringing up the birth rate.

TRENCH NEPHRITIS.

ALTHOUGH a good deal has been written concerning trench nephritis, little appears to have been exactly learned regarding it. In the *Medical Press* of December 26, 1917, Dr. I. C. McWalter points out that when trench nephritis is referred to that of the ordinary Flanders variety is meant. The Gallipoli or Salonica type is a different variety. The ordinary characteristic of it is that it is not really a "trench nephritis" at all, that is to say, McWalter is inclined to think that the trench is not essentially concerned in the production of the disease, though possibly there has always been the factor of an exhausted overheated man, subjected to a sudden chilling of the atmosphere, and in close proximity to newly turned earth. One characteristic feature of "trench nephritis" has been a loss of weight, although appetite was good and intake of food more than normal. Depression, restlessness, and indifference are also distinguishing symptoms and a certain mental lethargy is always present. Loss of albumin, which is seldom more than from a quarter to half an ounce daily, will not account for the loss of weight which accompanies the ingestion of a larger amount of food than ordinary. Few of the patients are drinkers, in fact the percentage of the consumers of alcohol in army hospital patients is very much less than one meets with in civil practice. As for treatment, McWalter is by no means in favor of the open-air treatment which is frequently so highly lauded. On the contrary, he has found that patients usually get worse in the open air even when the day is sunny; they prefer to be in a dark tent, and will complain of head-

ache if sent out for exercise. Little is to be said about the therapeutics of trench nephritis. McWalter is of the opinion that there is no specific. As routine treatment, he administers tincture of perchloride of iron, with nitrous ether and solution of acetate of ammonia. *Nux vomica* appears to be useful in other cases.

RECRUDESCENCE OF RABIES IN FRANCE.

THIS phenomenon was noted a year or more ago in the vicinity of Paris and explained by migration of rabid animals from the provinces in which, owing to the war, proper care of dogs was impossible. More recently a graduation thesis by Fiany (Bordeaux, 1917), has dealt with increase of the disease in the Gironde and Southwestern France. In the Gironde, veterinaries report that its incidence has quadrupled since the war began; while in 1916 the number of human beings treated at the Pasteur Institute at Bordeaux showed a three-fold increase, as far as cases from the Gironde are concerned. This increase is not to be found in France as a whole; in fact in some of the departments the disease has been stamped out. Hence it is difficult to determine the causes of this recrudescence, for neglect of animal care due to war must be the same in all localities. An investigation of the conduct of those held responsible for suppression of rabies may be required; and at the same time a general round up of stray dogs with impounding for observation purposes must be instituted. The problem of rabies in man is bound up with the future of the stray dog.

News of the Week.

State Quotas of Babies to be Saved During Children's Year.—The Children's Bureau of the United States Department of Labor which has initiated a campaign to be conducted during the coming year, beginning April 6, to save 100,000 lives of children under five years of age, has announced the quota of this number which each State should aim to save. The assignments are made on the basis of the infant population under five years of age according to the census of 1910. Owing to the fact that the registration of births and deaths is seriously deficient in some States the assignments may not be altogether accurate. The assignments range all the way from 60 in Nevada to 8,455 in New York and 8,318 for Pennsylvania. The number assigned to a large number of States ranges between two and three thousand. It is expected that the 5,000 or more local committees of the Child-Welfare Department of the Women's Committee will be able to carry the campaign to every community in the United States. This is looked on as essential to the success of the movement, for in the last analysis every community must save its own babies if they are to be saved.

City Ordinance Providing for School Lunches.—The Committee on General Welfare of the Board of Aldermen of New York City has proposed an ordinance for the establishment of a bureau to furnish lunches in the public schools. A hearing was held on this ordinance on February 13, at which time it was shown that according to the figures of

the Board of Health there were 218,000 seriously undernourished children in the schools of the city in December, as compared with 110,000 in December of the year before.

Columbia University Adds to Medical College.—The Trustees of Columbia University announce a gift of \$50,000 from an association of women physicians and a sum totaling \$18,000 from other donors which will enable the university to begin the erection of buildings in the Medical Department for the accommodation of women students. The new building will also afford additional laboratories for the college. This year has shown an increase in the registration at the College of Physicians and Surgeons, there being now enrolled 600 students, of whom 10 are women, as compared with 554 last year.

Health Crusade to Enlist Children.—The National Association for the Study and Prevention of Tuberculosis has planned to hold a pennant contest to enroll a million children in the National League of Children's Health Crusaders. Ten pennants have been offered in the local leagues in cities of the various population classes as rewards for the largest per capita membership. It is hoped that one million new members will be obtained by the end of the present school year. The object of the national association is to interest children in matters pertaining to health and in this way to lay better foundations for the health of the coming generation.

Proposed Amendment to State Health Law.—There is now before the Legislature of New York State, under the title "An act to amend the public health law in relation to reports of officials and employees to the State Department of Health which reads as follows: 'The Commissioner of Health shall take cognizance of the interests of the health and life of the people of the State and all matters pertaining thereto.'" The amendment written at the request of the Health Commissioner is as follows: "The written reports of officers and employees of the State Health Department on questions of fact under the public health law, or under the sanitary code, or any local health regulation, shall be presumptive evidence of the facts so stated and shall be received as such in all courts and places. The persons making such reports shall be exempt from personal liability for the statements therein made if they have acted in good faith."

Hospital for Palestine.—Announcement is made by the Women's Zionist organization that Mrs. Peter J. Schweitzer of Brooklyn has donated \$25,000 for building and maintaining a model eye hospital in Palestine, where trachoma and other eye diseases are prevalent. A medical unit is prepared to leave for Jerusalem as soon as passports and transportation can be obtained.

Antipneumococcic and Antimeningococcic Serums of Good Quality.—The Public Health Report, No. 6, February 8, 1918, states that in order that those who use antipneumococcic and antimeningococcic serums shall be assured that such of these serums as are sold in interstate traffic are suitable for therapeutic purposes, each lot of these products made by the various manufacturers is tested at the hygienic laboratory of the United States Public Health Service prior to being placed on the market. The quality of the antipneumo-

coccic serum is judged by its protective value against Type I pneumococci, using mice for test purposes. The antimeningococcic serum is tested by agglutination and complement fixation tests. Those products that prove satisfactory are passed.

Fordham Graduates Doctors.—In order to help fill the gap made by the war in the supply of doctors, Fordham University graduated 61 doctors on February 13, four months ahead of time. The doctors, however, had completed their course, having studied all last summer to make up the time. Those receiving prizes were Dr. Daniel J. Dolan, Dr. Harold T. Joyce, Dr. Augustus Wolf, and Dr. Joseph E. Conroy.

Pneumonia Deaths in New York Continue to Increase.—For the week ended on February 16 the deaths in the five boroughs of Greater New York numbered 1,738 from all causes, 373 resulting from pneumonia, as compared with 1,772 deaths from all causes for the previous week, of which 355 were due to pneumonia, making an increase of eighteen deaths from pneumonia over the previous week.

Health of Paris Improves as Result of Rationing.—Figures quoted from the *Weekly Bulletin of Municipal Statistics of Paris* show that the health of the French capital has distinctly improved under the restrictions in diet imposed by war conditions. For the months of June the deaths in Paris numbered 505, compared with an average of 903; for July, 562, compared with 815; for August, 585, compared with 706; for September, 587, compared with 688. In the winter the number of deaths more nearly approaches the average, owing to the fact that the winter maladies are less affected by food conditions. The *Bulletin* points out that there are other restrictions not of an alimentary nature that must be considered in accounting for the betterment of the general health. The decrease in the means of locomotion has made people walk more, and the reduction in street lighting has kept people at home and away from cafés and restaurants, which means fewer alcoholic excesses and fewer opportunities of contracting contagious diseases such as pneumonia and grippe. Finally, the putting back of the clock one hour during half of the year has helped in improving health in that people were out of doors and in the sunlight for a longer time. It has been noted that many people have grown thinner, owing to the restrictions put on bread, sugar, and pastry, and this has benefited that part of the population which each year furnishes the greatest percentage of deaths attributed to diabetes, arteriosclerosis, heart and kidney troubles. It is also notable that it is many years since so few consumptives died in Paris as during the past year. This class of invalids have not suffered from food restrictions as they are largely in hospitals where sufficient food has been supplied.

Compulsory Health Insurance Killed in Massachusetts.—The Special Recess Commission on Social Insurance appointed by the Massachusetts Legislature to consider Governor McCall's recommendations for compulsory health insurance reported January 15, 1918, in opposition to the establishment of a State system of compulsory health insurance, declaring such a system has few supporters, is opposed by laborers and employers alike, and is distinctly class legislation.

Campaign for Prevention of Insanity Urged.—The New York State Hospital Commission, in its annual report recently submitted to the Legislature, recommends vigorous State-wide efforts to prevent mental disease. The report shows that the insane cost the State \$8,382,000 in the year 1917 and expresses the opinion that nearly one-half the cases of insanity are preventable. Five definite steps for the prevention of insanity are recommended. They are: 1. Checking the excessive use of alcoholic liquors. 2. Checking the ravages of syphilis. 3. Informing the public more fully about mental diseases and teaching mental hygiene. 4. Steps to eliminate extreme poverty. 5. Extension of the out-patient departments of the State hospitals, with more free clinics for mental and nervous disorders and field agents to look after incipient and convalescent cases.

Dr. John A. Harris, who retired from the practice of medicine to undertake several business projects, has been appointed special deputy police commissioner of New York City, without pay, to regulate traffic. He has for some years made a study of traffic conditions and has plans for their improvement.

Dr. William S. O'Brien has been elected chairman of the Board of Health of Springfield, Mass.

Dr. Allan J. McLaughlin, who has been Commissioner of Health of the State of Massachusetts since 1915, has resigned to accept an appointment as assistant surgeon-general in the Federal Bureau of Public Health.

The Portsmouth (N. H.) Medical Society, at its annual meeting, on February 5, elected the following officers: *President*, Dr. A. C. Heffinger; *Secretary*, Dr. H. B. Hannaford; *Treasurer*, Dr. E. B. Eastman.

Dr. William M. Hillegas of Philadelphia has been appointed by Governor Brumbaugh a member of the Pennsylvania State Bureau of Medical Education and Licensure in succession to the late Dr. Daniel P. Maddux.

Congestion in New York State Insane Asylums.—The annual report of the State Charities Aid Association to the State Hospital Commission shows an unprecedented overcrowding in the State institutions for the insane. The total capacity of the thirteen State hospitals is rated at 27,890, and at the end of the fiscal year they contained 34,798 inmates, or an excess of 25 per cent. The overcrowding is reported to be worse in the institutions of the metropolitan district. The Charities Aid Association believed the State ought to appropriate at once \$20,000,000 to provide adequately for the insane and feeble-minded, the expenditure to run over ten years. The parole system has been applied to the State institutions for the care of the insane and has effected a saving of \$330,880 for maintenance, at the same time making room for additional patients. The State at the present time maintains thirty free clinics for nervous and mental diseases, with an average monthly attendance of about 500 persons. All the State hospitals employ field agents to look after paroled or discharged patients.

Amendments to the Sanitary Code of New York State.—The Public Health Council of the New York State Department of Health in reviewing

the amendments to the Sanitary Code made during the year 1917, calls attention to the amendment which adds chancroid, gonorrhea, and syphilis to the list of communicable diseases and makes obligatory upon every physician, when treating a patient affected with any of these diseases, to furnish such persons with a circular of information approved by the State Commissioner of Health and to instruct them in the precautions to be taken to prevent the communication of the disease to others. Other amendments requiring the reporting of acute anterior poliomyelitis and of all persons bitten by dogs suspected of having rabies. In order to inform the local health officers of the occurrence of deaths from communicable diseases other than tuberculosis, it was made the duty of the local registrar of vital statistics to report immediately to the local health officer, the name, age, and address of the deceased, whenever a certificate of a death from a communicable disease was received, also the name of the physician who filed the certificate. A model sanitary code for towns, villages, and third-class cities has been prepared and is recommended for adoption by local authorities. The State Commissioner of Health has been given authority to declare extracantonment zones about military camps and provision has been made for the monthly inspection of such zones by health officers. Regulations were also adopted providing for the inspection by health officers of boarding and lodging houses where people affected with tuberculosis were staying and also for the licensing of boarding houses making a business of boarding children under twelve years of age away from their parents.

Medical Society Elections.—THE ASSOCIATED PHYSICIANS OF LONG ISLAND held their twentieth annual meeting in Brooklyn, on January 26, when the following officers were elected: *President*, Dr. Lefferts A. McClallan of Brooklyn; *Vice-Presidents*, Drs. William A. Hulse of Bayshore, Henry Goodwin Webster of Brooklyn, and Harris J. Houghton of Bayside; *Secretary*, Dr. James Cole Hancock; *Treasurer*, Dr. Edwin B. Moore of Bay Shore.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY, at a stated meeting held January 16, elected the following officers for the ensuing year: *President*, Dr. Frank C. Hammond; *First Vice-President*, Dr. John W. West; *Secretary*, Dr. William S. Wray; *Assistant Secretary*, Dr. Elmer H. Funk; *Treasurer*, Dr. Edward A. Shumway; *Censor*, Dr. William M. Welch; *Directors*, Drs. William E. Parke, George A. Knowles, and F. Hurst Maier.

THE PHYSICIANS' MOTOR CLUB OF PHILADELPHIA, at its annual meeting, held January 21, elected the following officers for the ensuing year: *President*, Dr. S. Leon Gans; *First Vice-President*, Dr. John J. Robrecht; *Second Vice-President*, Dr. Charles A. E. Codman; *Third Vice-President*, Dr. Charles R. Haig; *Secretary*, Dr. Howard A. Sutton; *Treasurer*, Dr. Lewis H. Adler; *Directors*, Drs. Charles H. Harbaugh and Sylvester J. Deehan.

THE UTAH COUNTY MEDICAL SOCIETY at its annual meeting in Provo, on January 31, elected the following officers: *President*, Dr. Andrew J. Stewart of Salt Lake City; *Vice-President*, Dr. Joseph Hughes of Spanish Fork; *Secretary-Treasurer*, Dr. Walter T. Hasler of Lehi.

Charitable Bequests.—Under the will of Mrs. Teresa M. J. O'Donohue, St. Vincent's Hospital, New York, is bequeathed \$2,500 and the Misericordia and St. Joseph's hospitals each \$500.

A benefit opera given recently by the Ladies' Auxiliary of the New York Foundling Hospital netted that institution \$10,000.

By the will of the late William G. Ellis of Philadelphia the sum of \$1,000 is bequeathed to the Samaritan Hospital. By the will of the late Jacob Uditzky of Philadelphia one-fifth of a bequest of \$1,000 goes to the Mount Sinai Hospital and one-fifth to the Sanatorium for Tuberculosis at Eagleville, Pa.

War Industrial Diseases.—The meeting of the Academy of Medicine, to be held under the auspices of the Public Health Committee on March 7, will be devoted to a discussion of "The Prevention of Disease in War Industries." The topics to be presented are: (1) Extent and Importance of the Problem, by Dr. David Linn Edsall, professor of clinical medicine, Harvard University. (2) New Poisons in War Industries (illustrated by lantern slides), by Dr. W. Gilman Thompson, emeritus professor of medicine, Cornell University Medical College, New York City. (3) Methods of Prevention and Control, by Dr. Joseph W. Schereschewsky, director, United States Public Health Laboratory, Pittsburgh, Pa. (4) Aid from the Medical Profession, by Dr. Alfred Stengel, professor of medicine, University of Pennsylvania.

A New Game on the Doctor.—An ingenious scoundrel has devised a new plan for getting into a doctor's office during his absence and relieving him of instruments or other valuables which may be lying handy. A surgeon started out the other day to perform an operation at some distance from his office. After he had been gone a certain time an automobile drew up at his door and a well-dressed man jumped out in haste and told the maid who answered his ring that an instrument which the doctor greatly needed had been left and that he had come to get it. The maid in this instance, with unusual acuteness, refused the man admittance, and after much vain persuasion and threatening her with the doctor's wrath the man went off in his car. The same game has been played in some other cases with better success, and doctors and maids are hereby warned to 'ware the willing messenger.

Medical Staff Changes at Sea View Hospital and Sanatorium, Staten Island.—Dr. G. Kremer, formerly physician-in-charge of the Tuberculosis Admission Bureau, New York City, has been appointed superintendent. Dr. J. Dworetzky, formerly of the resident staff of the New York Municipal Sanatorium, Otisville, N. Y., has been appointed resident physician and designated acting deputy medical superintendent. Dr. M. G. Milan, formerly of the resident staff of the Otisville Sanatorium, has been appointed resident physician. Dr. Stanley D. Wang has resigned as resident physician.

Obituary Notes.—Dr. JOHN ALEXANDER GORDON of Quincy, Mass., a graduate of Harvard Medical School in 1871, died on January 25 at the age of 75 years.

Dr. WILFRED W. BROWNE, a graduate of the Baltimore Medical College in 1891, died at his home in Woonsocket, R. I., on January 28.

Dr. FRANK L. BURR, a graduate of the University of Pennsylvania Medical College in 1871, died of angina pectoris at his home in Rocky Hill, Conn., on January 23, aged 71 years.

Dr. NELSON HOYT CHAMBERLAIN of Oakland, Cal., a graduate of the Michigan Homeopathic Medical College in 1892, died in the Hahnemann Hospital, Chicago, Ill., following a stroke of apoplexy, on January 22, aged 50 years.

Dr. HENRY FLEISCHNER of New Haven, Conn., died of pneumonia at his home in that city, on January 20, aged 73 years. He was graduated from the Yale Medical School in 1878, and was connected with the New Haven and St. Raphael's hospitals.

Dr. CHARLES TAYLOR JEWETT of New York, a graduate of the College of Physicians and Surgeons, New York, in 1868, and for fifty years a practising physician, died on January 18 at the age of 71 years.

Dr. PATRICK J. CASSIDY, a graduate of Johns Hopkins University Medical School, died at his home in Norwich, Conn., on January 28, aged 43 years.

Dr. ALBERT H. VARNEY of Newfields, N. H., a graduate of the Harvard Medical School in 1857, died on January 15 at the age of 82 years. He was formerly assistant surgeon of the Second New Hampshire Regiment, and was elected to the Legislature in 1871.

Dr. REDINGTON STANHOPE, a graduate of the Western Reserve University Medical Department in 1880, died at his home in Lincoln, Neb., on January 19, aged 80 years.

Dr. WILLIAM CHILTON DAY of Danville, Va., died of pneumonia in the Danville Hospital, on January 25, aged 77 years. He was a graduate of the University of Virginia Medical College, and served as a surgeon in the Confederate Army during the Civil War.

Dr. THOMAS L. IRWIN, SR., a graduate of the Cincinnati College of Medicine and Surgery in 1865, died at his home in Jacksonville, Fla., on January 25, aged 81 years.

Dr. EDWARD A. MALSCH, a graduate of the Memphis Hospital Medical College in 1892, died of pneumonia at his home in Victoria, Tex., on January 27, aged 48 years.

Dr. WILLIAM E. RODMAN of Hodgenville, Ky., a graduate of the University of Louisville, medical department, died on January 25, aged 71 years. He was president of the Larue County Medical Association and Health Officer of Larue County.

Dr. JACOB FRANKLIN LEWIS, a graduate of the Eclectic Medical College, Cincinnati, in 1880, died suddenly at his home in Little Rock, Ark., on January 24, aged 65 years. He was an ex-president of the Eclectic Medical Society of the State of Arkansas.

Dr. CHARLES H. WILLIAMS, retired physician, died suddenly at his home in Hamburg, Ill., on January 23, aged 65 years.

Dr. EUGENE HAROLD JAMES died at Harrisburg, Pa., on January 27 at the age of 61 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1879 and he served for twenty years as surgeon to the Pennsylvania Railroad.

Dr. JOHN MARTIN CRAIG died of pneumonia at

Philadelphia on January 26 at the age of 55 years. He was graduated from the medical department of the University of Michigan in the class of 1898. He was a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, of the New Jersey State Medical Society, and of the American Medical Association.

Dr. ANNIE L. CONNER died at Philadelphia on January 29 at the age of 42 years. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1901. She was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. ERNEST FREDERICK LUHRSEN died at his home in Brooklyn, N. Y., on February 3, aged 42 years. He was a graduate of the Long Island College Hospital in 1899, a member of the American Medical Association, and the Associated Physicians of Long Island. He was on the staffs of the Lutheran and Brooklyn hospitals.

Dr. FREDERICK C. ROTH, a graduate of the College of Physicians and Surgeons, New York, in 1891, died at his home in New York on February 3, aged 49 years.

Dr. GEORGE W. CROSBY, a graduate of the New York Homeopathic Medical School in 1878, died at his home in Atlantic City on February 3, aged 66 years.

Dr. A. MILLIKEN of Placerville, Cal., a pioneer physician of California, died January 26, at the age of 85 years.

Dr. WILLIAM E. BUELL, chief surgeon of the San Francisco Iron Works Co., was shot to death by an employee of the company on February 4. He was a graduate of the College of Physicians and Surgeons, San Francisco, in 1900, and was 42 years of age at the time of his death.

Dr. FREDERICK CHILDS JONES of Basking Ridge, N. J., a graduate of the College of Physicians and Surgeons of Columbia University in 1877, died of pneumonia on February 9, aged 63 years.

Dr. ANNA McCULLOUGH died at Philadelphia on February 10 at the age of 86 years. She was a graduate of the Woman's Medical College of Pennsylvania.

Dr. GEORGE W. CROSBY died at Atlantic City, N. J., on February 7, at the age of 66 years. He was graduated from the Homeopathic Medical College and Flower Hospital of New York in the class of 1878.

Dr. DANIEL KARSNER died at Philadelphia on February 8, at the age of 65 years. He was graduated from Jefferson Medical College in the class of 1865, and he served as assistant surgeon in the United States Army during the Civil War.

Dr. ELLA ELIZA SEVERANCE died at Camden, N. J., on February 9 at the age of 61 years. She was graduated from the Boston University School of Medicine in the class of 1901.

Dr. THOMAS HENRY NORTHRIDGE, a graduate of the Long Island College Hospital in 1876, died at his home in Brooklyn, N. Y., on February 10, aged 67 years.

Dr. HOWARD BURHANS BESEMER died at his home in Ithaca, N. Y., February 8, aged 48 years. He was a graduate of New York University in 1891 and a Fellow of the American College of Surgeons.

Obituary.

THOMAS J. MAYS, M.D.

PHILADELPHIA.

DR. THOMAS J. MAYS died of apoplexy on February 14, 1918, at his home in Philadelphia. He was born in Lebanon County, Pennsylvania, on January 10, 1846. He was graduated from the Jefferson Medical College in 1868. After several years spent in general practice he went to Europe to study physiology and also diseases of the chest. Returning in 1885, he resumed practice and three years later was appointed professor of diseases of the chest at the Philadelphia Polyclinic Hospital, holding this position until 1902. In 1890 he assisted in organizing the Rush Hospital for Consumptives and was visiting physician there until he resigned in 1905. In 1908 he organized the Philadelphia Clinic for the Home Treatment of Consumption and was made medical director of the institution, which position he filled until his death. He was also visiting physician to St. Mary's Home for Aged Women and consulting physician to the Institution for the Feeble-minded at Vineland, N. J. He was a member of the American Climatological Association, the American Neurological Association, the Philadelphia College of Physicians, the Philadelphia County Medical Society, the American Medical Association, and the Pennsylvania State Medical Society. Dr. Mays was a voluminous writer, having contributed about 500 articles to medical periodicals and was the author of "Pulmonary Consumption, a Nervous Disease," "Therapeutic Forces," and "Consumption, Pneumonia, and Their Allies."

Correspondence.

THE LIGATURE BODKIN.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Some gentlemen appear to be interested in the author's substitution of a modified bodkin for the customary ligature carrier. In fact, their remarks upon the principle involved are complimentary; yet when it comes to a question of planning and of manufacturing the instrument of which they speak so kindly, it would seem to be a very wise policy indeed to avoid making an article to suit another's needs, but rather to furnish broad and sketchy directions so that each man unhampered may work out his own salvation, or at least may suit his own hand and may embody his own ideas. If this is done then any surgeon may make his own carriers and may find them satisfactory whether he wishes a straight, a $\frac{3}{8}$ curve, a $\frac{1}{2}$ curve, a $\frac{3}{4}$ curve, a long, a short, a slight curve, or an assortment of all, or of different kinds of straights or curves.

A needle holder is indispensable, therefore, when working with such a tool; if a necessity for using a ligature carrier should arise it is an advantage not to be compelled to lay down that holder, to take up a carrier and then to return to the holder again and over again. This advantage will clearly appear when there is something at hand that may be inserted into the needle holder where it will replace a ligature carrier and a something that may be sub-

stituted, changed, or discarded as simply and easily as an empty needle may be removed and may have its place filled with a threaded one.

Nowadays much stress is laid upon portability and cost. This stress would lead to the discarding or elimination of instruments. The bodkin will be found quite in line with this tendency of the times for it goes into the needle case, not among the instruments, and the space occupied by a carrier would be much more than several dozen bodkins could occupy. The cost of the bodkin should be five cents or less, and, in short, the carrier is one more instrument, while from a certain point of view the bodkin is simply one more needle, though the steel bodkin of the domestic needle book is not at all adapted to the end proposed. There is a sort of bodkin well known to the dry goods stores by the name of "Never-Slip." To this reference is made. Should anyone purchase a supply of this article he may make, with a hemostat and his fingers, any desired shape in a few minutes. As the suggestion for a standard type here is a working rule: (1) Cut off $\frac{1}{4}$ inch from each end, with scissors. (2) Bend the remainder into a half circle. Blunt edge, sharp edge, chisel edge, or pointed edge may be formed by rubbing upon a stone.

As for the needle holder probably any sort will do, though an Ermold will crush and bend the bodkin if undue force is used. The Richter has two flat places, just behind the knob and needle grasp, and these serve admirably. The other holders have given no trouble as yet. When in the grip of a holder, forceps, or hemostat, the bent bodkin may be used as a needle is used with following thread, or as a carrier with thread in advance. A figure-of-8 stitch gives but one knot to tie for every two stitches and will perhaps prove as expeditious as any mode of employing the little tool.

Three or more of such bodkins may be threaded by nurse or assistant (as needles usually are) and, in fact, numerous expedients will suggest themselves to the user.

DOUGLAS H. STEWART, M.D., F.A.C.S.

128 WEST EIGHTY-SIXTH STREET, NEW YORK.

DEATHS FROM AUTOMOBILE FUMES.

TO THE EDITOR OF MEDICAL RECORD:

SIR:—Four deaths from automobile fumes were reported in the New York newspapers during the last three weeks of December, 1917. The victims were Nat M. Wills, 43, a famous comedian; Dr. Martin G. Benedict, 61, a head school master; John and Vincent Dragone, 29 and 13, two brothers. There is hardly an automobile man who has not heard of other deaths or cases of temporary illness from automobile fumes.

The fumes are generated by the combustion of gasoline and oil, are discharged from the exhaust under the chassis of the automobile and contain poisonous gases. When the combustion of gasoline is incomplete the most dangerous gas given off is carbon monoxide. Incomplete combustion is due to missing fire on account of an inferior quality of gasoline, improper mixture of air ("rich mixture") or defective machinery.

Persons may be overcome by being close to the exhaust or in any part of a garage in which the

fumes are discharged; they may be exposed only a fraction of a minute. It happens most frequently in small garages and in the winter time when the doors and windows are kept shut; but it can also occur in the summer time and in the open air if a person is close to the exhaust—for instance, while working under a car or putting on a back tire. Inexperienced men are more frequently overcome because they let their motors run and discharge fumes unnecessarily.

To prevent poisoning from automobile fumes the following precautions should be taken: Have good ventilation; do not run the motor in a small, insufficiently ventilated garage; do not run it unnecessarily; put alcohol and glycerine or some other non-freezing mixture in the radiator; use good gasoline; do not use too much oil. If you must work in a confined space wear a gas mask or attach a rubber hose to the end of the exhaust to carry the fumes off outside. A warning sign should be posted in every garage. Future improvements in the automobile to prevent sickness and deaths from automobile fumes might be a tank to absorb the poisonous gases or a practical electric battery for out of town use.

5. A Study of the Kidney Function in Senility. W. C. Rappleye.

5. A Study of the Kidney Function in Senility.—W. C. Rappleye states that the results of the present study were obtained from a group of patients whose ages ranged from 70 to 88 years. These patients were free from gross evidences of renal insufficiency or other compromising conditions (fever, edema, dyspnea, anemia of note, etc.) and most of them were active workers. Under the conditions of diet and hospital routine at the Foxboro State Hospital the upper normal value of blood urea nitrogen is considered as 15 to 16 mgm. per 100 cc., the blood being drawn before breakfast, 12 to 14 hours after the preceding meal. Fifty per cent. of the cases studied showed a moderate degree of retention, using the blood urea nitrogen figures as a criterion. Fifty per cent. of the cases showed a systolic blood pressure of 160 mm. or over; a higher percentage showed a diastolic pressure of 85-90 mm. or over. The blood pressure readings cannot be said to be related to either the blood urea nitrogen or to the rate of elimination of phenolsulphonethalein. In 27 cases in which the elimination of phenolsulphonethalein was determined, 13 showed a value of 40 per cent. or lower; 9 of these were 35 per cent. or lower. A low value of elimination of the dye is associated for the most part with an elevated blood urea nitrogen. A good excretion is related for the most part with a relatively low blood urea nitrogen. Twenty-five per cent. of the cases showed albumen in the urine. There were no cases of glycosuria or hematuria. Practically all of the cases showed casts—a customary observation. Sixty-six per cent. of the cases showed either an elevated blood urea nitrogen or a depressed value of phenolsulphonethalein elimination (40 per cent. or lower). If one disregards the findings of only a few casts in the urine and disregards the blood pressure also, it can be said that, in the group of patients studied, about 70-75 per cent. show easily demonstrable evidences of kidney

insufficiency. It will be noted that in this group there are several cases showing a relatively low blood urea nitrogen and a good renal function, but which have a considerable elevation of blood pressure, the so-called cases of "essential" hypertension.

6. **Blood Pressure in Head Injuries.**—H. M. Armitage points out that blood pressure readings are only of negative value in head injuries where compression of the brain with medullary involvement has not occurred. In severe fractures of the base with widespread hemorrhage, blood pressure readings are valueless. In all other fractures of the skull with compression and medullary involvement, blood pressure readings form one of our most important symptoms, but, contrary to all teachings, he believes the systolic pressure to be of no value whatever as a diagnostic measure in determining the degree of compression of the brain and aiding in the decision as to the advisability of an operation. These cases show conclusively that the pulse pressure is proportionately high in cases of traumatic compression of the brain and the more serious the compression the higher the pulse pressure until the last stages when vasomotor compensation begins to fail. They also prove that the pulse pressure ascends as the pulse rate descends in each case until finally the pulse pressure becomes greater than the pulse rate and when this has occurred compression has always been present. It would be folly, however, to wait deliberately for this phenomenon to occur before operating in cases where a proportionately high pulse pressure was rising and the pulse rate falling. The choice we make in deciding whether or not a patient should be trephined must be made with a moderation of counsel and temperateness of judgment. Under such circumstances the final decision must always be formed from the study of the entire group of symptoms, but he unhesitatingly asserts that of these symptoms the most important one is the frequent estimation of the pulse pressure in its relation to the pulse rate and systolic and diastolic pressures. In view of the fact that we may be called upon to treat an enormous number of head injuries during the present war and some of these will be borderline cases, it is altogether right that we should now undertake a minute study of the blood pressure findings in these injuries so that we may classify those types of injuries in which we may expect the sphygmomanometer to be of no aid whatever and those in which it will be of use.

3. **Pregnancy and Pulmonary Tuberculosis, with a Report of One Hundred and Three Cases.**—Charles C.

Norris and H. R. M. Landis point out that years ago pregnancy was supposed to exert a favorable influence on the course of pulmonary tuberculosis, and that the fact that the cases were not closely followed is probably the chief reason for such a view ever having been held. Their results show that the combination of pregnancy and pulmonary tuberculosis is a frequent one. Pulmonary tuberculosis exerts little or no influence against conception. Pulmonary tuberculosis exerts but little influence on the course of pregnancy, and except in the advanced stages exerts little or no influence toward causing abortion, miscarriage, or premature labor. About 20 per cent. of mild, quiescent pulmonary tuberculosis, and 70 per cent. of more advanced cases exhibit exacerbations during pregnancy or the puerperium. Marriage is worse for tuberculous women than for tuberculous men, owing to the dangers incident to pregnancy. Unless the pulmonary lesions have been quiescent for a moderately prolonged period, tuberculous women should not marry. Tuberculous women should not become pregnant unless the disease is in the first stage, and has been quiescent for a minimum period of two years. It is as yet impossible to determine with certainty which patients will bear the added strain of pregnancy well and which badly. We must individualize our patients. Moderately extensive lesions, recent activity, the development of secondary lesions, especially laryngeal involvement, loss of weight, fever, hemorrhage, sweats, lack of vigor, and inability to obtain proper treatment are ill omens whereas, the reverse are more favorable. Prior to the fifth month of pregnancy, the uterus should be emptied if the disease manifests evidence of becoming active, or if the lesions are extensive ones or laryngeal involvement occurs. Curettage during the first six or eight weeks, and in the latter cases vaginal hysterectomy, are as a rule the preferable methods. Interruption of pregnancy does not insure an amelioration of the pulmonary condition, but does definitely improve the prognosis. About 65 to 70 per cent. of patients, prior to the fifth month of pregnancy, will be definitely improved by the emptying of the uterus as soon as acute symptoms arise, provided proper after-treatment is carried out. Late intervention has given less satisfactory results. Sterilization is rarely justifiable. After the fifth month of pregnancy, it is generally advisable to treat these patients expectantly. Labor should be made as easy as possible. For this end, induction of premature labor two weeks before term is often advisable; rarely, if ever, should they be allowed to go beyond term. At labor, forceps or version is usually indicated. Infants should not be nursed by tuberculous mothers, and should be especially guarded from infection. Hygienic and dietary treatment should be employed at all times. These patients should be kept under close observation and should be examined by a competent internist at regular and frequent intervals. In the great majority of cases the tuberculosis precedes the pregnancy. Even in those cases in which the symptoms are first observed during pregnancy, infection has generally occurred prior to conception, and an exacerbation during pregnancy has directed attention to the pulmonary condition. They especially urge that all pregnant women giving a history at all suggestive of pulmonary tuberculosis be subjected to a thorough examination by a competent internist at the earliest possible date. Only in this way can the proper treatment be instigated at the time when it is most valuable. It is doubly important that tuberculous pregnant women shall be given the same care as the nonpregnant person as far as rest, hygiene, diet, etc., is concerned.

5. The Treatment of Staphylococcal Infection by Stannoxyl: Furunculosis and Acne (Method of Grégoire and Frouin).—Arthur Compton brings to mind the fact that Frouin, in pursuing his interesting researches on the action in vitro of metals on different bacteria, has investigated the influence of tin and its derivatives on the growth of staphylococci. With Grégoire he has established that this element, its chloride, or its oxide, when added to ordinary bouillon culture-medium, strongly inhibits the growth under anaerobic conditions of staphylococci; while under aerobic conditions the growth of staphylococci is not hindered, but the virulence of the microbe is diminished. That fact, coupled with the observation coming from the district of Beauce that furunculosis is an unknown affection among tin-workers of the region, formed for Frouin and Grégoire the starting point for testing in vivo the therapeutic value of tin in staphylococcal infections. They found that intravenous injection of the chloride or hydroxide of tin in the rabbit, twelve hours after intraperitoneal inoculation of virulent staphylococci, retarded the death of the animal by several days. As a result of these experiments Grégoire and Frouin have given us for the treatment of lesions of staphylococcal origin the preparation stannoxyl, which is a combination of metallic tin and its oxide, entirely free from lead, a drug which, already in France, has given such promising results in the treatment of staphylococcal infections (acne, furunculosis, etc.). Compton gives the history of seven cases, including furunculosis, acne, and infective dermatitis, which he treated with this method of treatment. The following is an account of one of the cases. Private B., aged 21, laboratory attendant. Very troublesome acne on face since the age of 12. Condition showed weekly periodicity, in that about once a week there appeared a widespread crop of papules all over the face, eventually becoming pustular, which was most distressing. Between August, 1916, and April, 1917, patient had continuous course of treatment with autogenous vaccine (*Staphylococcus aureus*) at more or less weekly intervals, the doses ranging progressively from 50 millions to 5000 millions, and that without the least benefit. Vaccine treatment was, therefore, abandoned, and treatment with stannoxyl begun on June 23, 1917, and continued, 8 comprimes per day, till August 6, during which time some 350 comprimes were taken. The condition rapidly improved with stannoxyl treatment, but between July 8 and 14 patient visited his home in Yorkshire, "on leave," and while there he had a more or less full-blown attack. On account of this, on his return Compton continued him on treatment much longer than appeared necessary after his condition had again cleared up. For a month after treatment was suspended, on August 6, there was no return of the weekly attacks, but occasionally a papule would appear on the forehead, which quickly disappeared, the rest of the face remaining quite clear. Owing to the return of some six papules on the forehead, cheeks, and neck on September 26 the patient was again put on stannoxyl, 6 comprimes per day. Anew there was an immediate response to treatment; inside a few days condition quite cleared up. This patient's condition being now so perfectly under control by stannoxyl treatment, it is hoped by successive courses of the drug eventually to completely cure him of his complaint. Up to the present patient has taken in all 410 comprimes, about 100 grains, of stannoxyl.

The results appear to show in these cases that stannoxyl affords a sure and efficient method of general treatment for such staphylococcal infections as furunculosis and acne. The beneficial effects are felt sometimes two days after beginning of the treatment, and in some cases the cure seemed to be obtained within five or six weeks from the beginning of the treatment, and in even a shorter time in furunculosis cases.

2. Acute Yellow Atrophy in Syphilis.—Stuart McDonald reports the rare experience of having come across five cases of acute yellow atrophy of the liver in syphilitic subjects in the postmortem room, all within two months. These cases had been treated by "salvarsan" preparations and mercury, and practically all had received a full course of intravenous injections of salvarsan, coupled with the usual intramuscular injections of mercury. The diagnosis had previously been made by the Wassermann test and on clinical grounds. These cases were not of undue severity, and showed no special symptom of importance till a sudden onset of jaundice was noticed, without at first any special disturbance, the disease suggesting nothing more than an ordinary catarrhal jaundice. At a varying period of from two to eight days, however, acute symptoms appeared with dramatic suddenness. They were ushered in by a period of wild excitement and increased icterus, with hematemesis. The patient rapidly passed into coma, and death occurred in the five cases at periods of one to four days from the onset of the acute symptoms. The urine was markedly bile-stained, and in each case showed tyrosin; in some leucin was also demonstrated. In four of the cases diminution in the size of the liver was demonstrated during life. Icterus gravis of a degree of acuteness was presented in these cases. The morbid anatomy and histology presented as striking results as the symptoms. Intense necrosis rather than fatty degeneration of the liver parenchyma was found, the bile duct epithelium largely escaping. Though "red" areas were microscopically present in the liver, the condition had been so acute that in most cases the "yellow" areas preponderated. In each case there had been widespread hemorrhages in the serous membranes with a special hemorrhagic infiltration of the lungs. The kidneys showed an intense degree of fatty change, and there was noticed also a varying degree of intestinal catarrh. Bacteriological examination has, in contrast to what has been hitherto found in similar cases, yielded some interesting results which may prove of prime importance in relation to the etiology of the condition. Cultures from the heart blood and lung have given copious growths of organisms apparently of the *coli*-typhoid type, with some definite cultural characteristic features and pathogenic properties. These organisms have not been fully investigated as yet, and a further report will be made. The bacteriology of acute yellow atrophy has so far been very indefinite, on account of the power of the liver for resisting microbial invasion from the alimentary canal. The isolation of the causal organism under these circumstances, if there be one, must not be expected to be an easy matter. That infection of some kind apart from syphilis plays some part in the etiology of acute atrophy has long been held. In a large number of recorded cases some previous intestinal catarrh has been noted. McDonald applies these points to his cases as follows: Here are five typical cases occurring together in a limited period; all have been syphilitic subjects, and all have been treated with salvarsan preparations *plus* mercury. It is remarkable that though similar cases amounting to thousands have been treated by the same methods, such a complication as this one has not been observed until now. This would seem to point to some other factor having been introduced. There is no evidence that the salvarsan has materially altered, at least in the last three years, and the syphilitic toxin and mercury factors may be taken as constant. Also, with this in each case there was found at the post mortem examination microbial infection of a special type. There would appear at least to be a *prima facie* case for regarding this infection as being the new factor which, acting on livers previously damaged by the syphilis, and possibly arsenic *plus* mercury, has completed the damage to the liver cells, and allowed autolysis of the tissue, which appears to be the essential liver change, to occur. Some such combination of circumstances might account for

the rarity of the disease. It should be noted that neither clinically nor pathologically do the cases observed bear any close similarity to cases of spirochetal jaundice.

Experiments with Malaria in Wartime.—F. Munk informs us that in a typical case of malaria the only certain diagnostic index is the presence of the specific organism in the blood. This should be sought for before the exhibition of quinine. The most common mistake in diagnosis is that with Volhynia fever. The writer prefers to treat these cases with repeated doses of quinine, rather than with massive doses as recommended by Robert Koch. The latter have only been used at the beginning of the treatment. Therefore, Munk prescribes one gram of quinine four hours before the supposed time of the paroxysm and then continues with a daily dose of 1.20 grams in divided doses for the first six days. He alternates the exhibition of the drug every three days—three days with and three days without quinine in cases which will be prolonged. The centralization of malarial patients in the hands of special physicians would offer great advantages from the therapeutic viewpoint. Quinine is to be exhibited in solution as it is thus better tolerated than in compressed tablet form. Salvarsan radically controls the paroxysms of tertian fever but its action is not of any duration. In order to prevent dissemination of malaria, the writer proposes to search out and isolate all germ carriers.

On Tuberculosis.—E. Schloss found that in a ward of nursing babies a large number of positive reactions took place upon the occasion of a general test with tuberculin. A carefully carried out investigation showed that the epidemic was due to a nurse who was in advanced pulmonary tuberculosis and who had hidden her disease. The tuberculin test was positive in all the children of this service with the exception of two babies who were breast fed by their mothers. In a series of babies in a ward where this particular nurse had only temporarily substituted 33 per cent. of the subjects were infected. Finally, in a third series where she had given her care for only the briefest period a single baby presented a positive reaction.

Experiments with the Toxins and Antitoxins of an Anaerobic Organism Belonging to the Malignant Edema Group.—T. Klose has injected guinea pigs, rabbits, and mice with a toxin derived from a culture of an anaerobic organism resembling that described by Novy. The picture offered by the writer is that of an extensive edema, either cutaneous or pulmonary, according to the route followed by the infection, and accompanied by symptoms of an acute intoxication. This toxin, a product of the metabolism of the organism under discussion, is thermolabile, as by heating at 58° C. for one hour it is rendered innocuous. Utilized as an antigen, it immunized both guinea pigs and rabbits against a lethal dose of the same toxin. The combination of the toxin and serum of immunized animals follows the law of multiples, and therefore should be looked upon as a true bacteriotoxin. The antibodies obtained from rabbits protected other rabbits from the lethal effect of large amounts of the toxins at the dose of from 2 to 3 c.c. of antitoxic serum.

The Principles of Wound Treatment.—Wederhake offers the following advice after having examined many methods of wound treatment, which he gives to the world as quite original. Free use of tincture of tannic acid for preventing injection of wounds; the use of a concentrated watery solution of potassium permanganate for suppurating cutaneous lesions. Injections of turpentine in the gluteal muscles should be resorted to in streptococcal or staphylococcal injections, and no suppuration arises at the point of injection. Open-air treatment of wounds, they being protected only by a layer of gauze. The use of skin grafts or grafts with hernia sacs in order to accelerate the closure of

large torpid wounds. In gas abscesses and gas gangrene the parts should be covered with a layer of sugar and naphthalene after suitable incisions have been made.

The Etiology of the Weil-Felix Reaction.—G. Wolff found the proteus X19 in the circulating blood. However, he is of the opinion that this organism is not the causal agent of typhus fever, and that when it is present the case is one of mixed infection, symbiotic with the etiological virus. As in the case of Widal's reaction, the Weil-Felix reaction becomes positive at the time when the bacilli circulating in the blood have become fewer. The reaction remains positive a long time after the decline of the disease at the rate of 1/50 to 1/100. This does not imply that there is still an active infection going on, as it may simply indicate the remaining effects of a former infection.

Quinine in the Human Organism.—G. Giemsa and J. Halberkam have experimented with the procedure described by Teichmann and Neuschlotz (*Archiv für Trop. Hygiene*) for urine analysis from the standpoint of its quinine content. The procedure is useful for estimating if the patient has received enough or not enough of the drug. On the other hand, quantitative analysis requires the isolation of the alkaloid. The writers have not observed, as has been maintained by Teichmann and Neuschlotz, that elimination is different in those accustomed to quinine from subjects not used to taking it.

An Epidemic of Typhus Fever in Prisoners in Russia.—Petschacher relates his souvenirs of an epidemic of typhus occurring among prisoners of war in oriental Siberia. As he was short on bacteriological implements, his study has been purely clinical. The disease occurred in 2200 men out of a total of 9000 (24 per cent.). Among the physicians the proportion was 65 per cent.; the nurses were more exposed and gave 80 to 90 per cent. of infection. The mortality was in general 34 per cent.; among the doctors only 18 per cent. Petschacher supposes the duration of incubation to be about a fortnight. The disease commences with general symptoms, the appearance of splenic hypertrophy on the third or fourth days, the exanthema on the fourth day. Usually the latter appears on the hands and afterwards extends to the arms and trunk. Hearing is often dulled from the beginning of the disease and continues so well into convalescence. The complications most commonly met with were parotiditis, inflammation of the thyroid gland, occasionally median otitis, and bronchopneumonia. Nervous symptoms were not infrequently noted, these being of various kinds, and even psychoses occur. Typhus fever appears to predispose the patient to other infections, such as erysipelas, smallpox, diphtheria, and typhoid fever. The epidemics related by Petschacher suddenly ended at the beginning of May, this time coinciding with a change of season and with it the disappearance of body lice. [This is an account of one of the very numerous epidemics of typhus occurring in the Austro-German camps since the beginning of the war. The writer of the article neglects to state the number of Russian medical men who died of the disease, the custom so far having been to hand over all epidemics in prisoner's camps to the care of medical men retained as prisoners, as was done at the Wittenberg camp when the Prussian Dr. Aschenbach and his medical colleagues ran away and left the care of the typhus patients to the British physicians.]

LXXXVII, 1917.

Prognosis of Paratyphoid B. Fever.—Shubert states that since paratyphoid fever is characterized by temperature which is neither very high nor of long dura-

tion the prognosis is comparatively good—much more favorable than in typhoid of the same degree of severity. But this affection can by no means be reckoned as benign, as shown in the author's cases. His general mortality was from 1 to 2 per cent., or if we deduct the vaccinated cases, 2.8 per cent. In the material of certain writers, the mortality has attained 6 per cent., and even in a portion of the author's cases it was 5 per cent. The extensive dissemination of the bacilli of paratyphoid B., its persistence as a noxious influence, its tendency to appear in epidemic incidence, renders the question of wholesale prophylaxis extremely serious. Much interesting information on this subject is to be found in Simont's article on the paratyphoid fevers, published in 1916. This author states that, thanks to systematic inoculation, this disease has been sharply cut down. It has flourished to a threatening extent, especially after the battle of the Marne, when the French armies captured the territory which was formerly held by the Germans; among whom the disease appeared to have been spread by the extensive use of canned provisions and apparently despite the triple vaccinations.

Relapse of Scarlet Fever in an Adult.—Byelenka quotes from literature a large number of cases of relapsing scarlatina and adds one of his own. The patient was a married woman of 23. The fever curve shows that the acme was reached on the second and third days; after which there was a gradual fall, until on the 12th and 13th days the temperature reached below normal. On the 15th day, however, it suddenly shot up to 103.5°, reaching its maximum on the 18th day, with a sudden drop to subnormal on the 20th day. During the next few days there were slight fluctuations until the 26th, when it became permanently normal.

Le Progrès Médical.

The Conception of Somnambulism.—Bernheim states that somnambulism is often an acted dream. As in all dream states sleep is incomplete. The active mental faculties are indeed suppressed, while the passive cerebration which corresponds to imagination holds full sway. In the waking state the imagination also runs riot, but is under censorship. When the latter is removed imagination does not awaken reflection; attention is absent. In a dream a dreamer may be only a spectator or an actual participant. In the latter case emotions enter into the dream, and if these are sufficiently distressing the subject awakens with a nightmare. If the dream is sufficiently personal the dreamer enacts it. Thus the servant girl rises in her sleep and sweeps or cooks. This active somnambulism, however, is no mere dream. The subject, really awake, acts under the suggestion of the dream. The brain is not sleeping, but under domination. Reason and judgment have full play, as in the case of the cleric who rouses himself in his sleep and critically edits his sermon. Somnambulism is only suggestion, with the mental and bodily functions in full activity. The autosuggestion in these cases can usually be traced to some unpleasant mental experience. In some cases the somnambulism is vividly remembered. The subject will not believe that he has fallen asleep before performing these acts. In others there is total amnesia, while in still others a few details of the somnambulist performance may be recalled. When amnesia is complete—and the popular belief has this type in mind—a double consciousness is conceivable. But amnesia is equally attendant on simple "static" dreams—in many of these there is complete oblivion. The difference between the passive and the acted dream is not one of simple recollection. The action of fever is a familiar one—a normal, nonsuggestible person attacked by typhoid or pneumonia may get out of bed and lock the door or windows in connection with a dream of burglars. The author cites the case of a non-hysterical woman whom he treated for dilated stomach and gastralgia with suggestive therapeutics. As she was of the type which readily falls asleep, the author hypnotized her by simply closing her eyes; after which she carried on an animated conversation with him, gossiping about household affairs like a woman fully awake. The author sought in vain to make her do certain things by suggestion, but her reason was awake,

and she told him that such things did not "take" with her. Soon after this he roused her from the "sleep," although as a matter of fact she had never been asleep. Nevertheless, she showed complete amnesia, and cherished an illusion of sleep. In like manner Bernheim repudiates the term "automatic movements" as applied to these subjects. There may be an illusion of automatism, but the mental faculties are all active. Suggestibility is not a pathological but a physiological manifestation.

Revue médicale de la Suisse romande.

December, 1917.

Eosinophilia of the Lymph Nodes After Resection of the Sciatic Nerve.—Loewenthal writes a second paper on this subject, but thus far deals only with experimental pathology of the rabbit, in which resection of a sciatic nerve is followed by hypertrophy of the popliteal ganglia of both sides with local eosinophilia. The blood shows more eosinophiles than normal, and the popliteal gland on the nonoperated side, although notably enlarged, shows fewer eosinophiles than its fellow of the operated side. Blood eosinophilia reaches a maximum on the third postoperative day. The nerve was resected at the level of the coxofemoral joint, and at least 1 cm. of nerve was removed. The immediate consequence to the gland was hyperemia with some extravasation. The sinus of the gland showed dilatation, and the gland was also edematous. Hyperplasia was not in evidence until about the seventh day after resection. Collateral lesions were trophic ulcerations of the paws. Hyperplasia in some cases represented a 24-fold increase of weight over the normal. In some cases, at least, the gland of the operated side enlarged much earlier than its fellow, and its weight was notably in excess of the latter, but in other examples the differences were much less marked. Did the eosinophiles proceed from the extravasated blood? Arguments are given *pro* and *con*; the alternative would mean formation from pre-existing lymphocytes in the gland. Weight of evidence notably favors the blood hypothesis.

Hypertrophic Osteo-Arthropathy of Pulmonary Origin.—Guye reports a case of this affection. Doubtless the majority of practitioners regard "drumstick fingers" as an isolated phenomenon, but radiographers have long known that the affection is more or less generalized. Nevertheless, it is a rare affection, and in one series of 8000 consecutive radiograms but one case was enumerated; despite the fact that 160 articles had been devoted to the subject when Fraügenheim's work on bone diseases in children was published. The author's case was in a man of 42 who came from a tuberculous stock, but who had been healthy until the advent of a peripleuritic abscess. The pus in addition to pyogenics was also tuberculous, as shown by animal inoculation. The abscess cavity, which was associated with empyema, did not close up under drainage, and the general health failed. Within three years from the earliest symptoms patient presented drumstick fingers and an analogous deformity of the toes. Attempts were made to secure improved drainage, and were followed by slight general and local improvement, which, however, was short lived, and followed by implication of the terminal end of the radius, and a similar process was evident in the malleolar region. Patient died of pulmonary infarcts and autopsy was refused. The author regards the lesions as trophic, although the mechanism is still obscure. In 1903 Berent saw in these lesions the result of a toxic neuritis which could be directly or only indirectly responsible for the muscular atrophy present.

Special Form of Melanosis from Deficient Diet.—Riehl believes that he has seen a condition in Austria which is affiliated with pellagra. Numerous subjects in a restricted area exhibited a peculiar bronzing of the skin, accompanied by desquamation and hyperactivity of the skin-glands. The pigmentation was continuous over the face and neck and occurred in spots elsewhere on the skin. No other symptom was present. —*Nederlandsch Tijdschrift voor Geneeskunde.*

Book Reviews.

PLAIES DE LA PLÈVRE ET DU POUMON. By R. GRÉGOIRE, Professeur Agrégé à la Faculté de Paris; Chirurgien des Hôpitaux et A. COURCOUX; Médecin des Hôpitaux de Paris. Avec Figures et Planches hors Texte. Collection Horizon. Prix, 4 francs. Paris: Masson et Cie., 1917.

AN important departure in the literature of thoracic surgery is the complete subdivision into uninfected and infected wounds. Even in the absence of all infection lung wounds present the most serious complications, as hemothorax, pneumothorax, open thorax, hemoptysis, emphysema, aseptic serothorax, absorption fever, fractures, and lesions of neighboring organs. Were there no virulent germs in the world thoracic surgery, in so far as it relates to traumatism, would still constitute a most important object of the surgeon's art. The section on infected wounds deals chiefly with empyema, abscess and gangrene of the lung, bronchopneumonia and suppurations in the mediastinum. Under surgery subjects of primary importance are foreign bodies in various portions of the thorax. In many respects the subject matter is so novel that no brief review can do it justice. Nevertheless, pressure differences, intratracheal insufflation and the like seem to be wholly ignored in operations. The work will undoubtedly be translated into English.

THE CLINICAL PATHOLOGY OF THE BLOOD OF DOMESTICATED ANIMALS. By SAMUEL HOWARD BURNETT, A.B., M.S., D.V.M., Professor in Comparative Pathology, New York State Veterinary College, Cornell University, Ithaca, N. Y. Second Edition, Revised and Enlarged. With Four Colored Plates and 23 Figures. Price, \$2.25. New York: The Macmillan Company, 1917.

THIS book is intended primarily for the veterinarian, but is specially useful to research workers who have occasion to use any of the domestic animals for experimental work. It is a plain statement of the facts, and contains 160 pages, divided into 11 chapters. The first three chapters are concerned with methods of examining the blood in animals, with the morphology of the formed elements, and with the normal blood findings in the horse, cow, sheep, goat, dog, cat, swine, rabbit, guinea-pig and domestic fowl. Chapter four is devoted to a consideration of the pathological variations in red corpuscles and hemoglobin; chapter five to the influences affecting leucocytes. The remaining part of the book deals with the general and special pathology of the blood in the various diseases of the animal. The text impresses one as being thoroughly scientific and up-to-date in every respect. An excellent feature is the comprehensive list of references at the end of each chapter. There are 23 figures in the text and four colored plates. The book is written in clear and concise style and is well printed on good paper.

DIAGNOSTIC SYMPTOMS IN NERVOUS DISEASES. By EDWARD LIVINGSTON HUNT, M.D.; Assistant Professor of Clinical Neurology, College of Physicians and Surgeons, the Medical Department of Columbia University, in the City of New York; Visiting Neurologist, City Hospital; Associate Consulting Neurologist to St. Luke's Hospital; Consulting Neurologist to the Lincoln Hospital, the Workhouse, and Penitentiary; Member of the American Neurological Association, and of the New York Neurological Society, etc. Second edition, revised. Price, \$2.00 net. Philadelphia and London: W. B. Saunders Company, 1917.

THIS book is avowedly a help to the study of nervous diseases, not a complete discussion of them, and the author has accomplished his purpose well. Books like Dr. Hunt's are all too few; it is far easier to compound a weighty tome where the paving-blocks of weighty extracts from other men's books are held together by the thin cement of original comment than it is to write a book that expresses the author's own viewpoint. For the book as a whole we have nothing but praise; we can, therefore, cheerfully take exception to certain details. The chapter called "The Examination of a Nervous Case" might well have been omitted, for it consists of little more under each heading than a reference to the chapter of the book dealing

with the subject in question. The outline of a clinical examination is good, but should come logically at the end of the book. An attempt is made in Chapter VI to discuss diseases of the spinal cord, but the author is cramped for space. In this second edition, among other things, a chapter on the cerebrospinal fluid has been added where, we regret to note, the sitting posture in lumbar puncture is given preference. The weight of authority is unquestionably in favor of the reclining posture, and it is too bad that in a work intended for students this mistake should have been made. However, the book as a whole fulfills its purpose admirably: the chief neurological symptoms are given clearly, many aids to diagnosis are described, there are many good illustrations, and the author has a clear, forceful way of putting things. Altogether a work which the beginner in neurology should not be without.

BUILDING HUMAN INTELLIGENCE. By ARNOLD LORAND, Physician to the Baths, Carlsbad; Author of "Old Age Deferred" and "Health Through Rational Diet." Translated from the German by PHILIPP FISCHER, M.D., Acting Associate Professor of Histology and Embryology, University of Pennsylvania. Price, \$3.00 net. Philadelphia: F. A. Davis Co., 1917.

WHEN, in the preface of this book, we read of insanity "breaking out" as if it were an erythema, we fear the worst, nor are we reassured by the writer's constant allusion to "plain human common sense" and his predilection for the adjective "rational." The book as a whole is a curious mixture of medievalism, materialism, superstition, and fallacy, compounded in a quasi-popular vein. It would be impossible here to illustrate all its faults, but we can quote a few of the statements made in its pages: "Mental diseases may originate from adenoids" (p. 46); "The nose is a protecting organ for the brain" (p. 47); "A milk diet is most favorable to the thyroid" (p. 188); "The actions of the insane are done without thinking" (p. 255), and "Mental disease almost always results as a consequence of great error or negligence in the mode of living" (p. 144). We should be sorry to see the views expressed in this book gain popular credence.

THE SURGICAL CLINICS OF CHICAGO. Volume I, No. 4, August, 1917. Octavo of 207 pages with 71 illustrations. Published bi-monthly. Price per year, paper, \$10.00. Philadelphia and London: W. B. Saunders Company, 1917.

THIS volume contains reports of clinics by fifteen surgeons and covers a wide range of subjects. Beck makes a plea for the employment of the transperitoneal route in certain cases of nephrectomy. Ochsner and Speed each present cases of cranial surgery; Eisendrath gives an instructive talk on the diagnosis and treatment of common-duct calculi, with special reference to overlooked common-duct calculi; while various other surgeons discuss interesting cases in the fields of aural, genitourinary, orthopedic, and general surgery.

The volume shows many evidences of not very careful proofreading. For example, we find that Ochsner uses "knawing" forceps; while the last portion of the legend under Fig. 291 states that the separated anterior end of semilunar cartilage is lying between "fibia" and tibia. However, the book will well repay careful reading as well as proofreading.

A CLINICAL TREATISE ON DISEASES OF THE HEART FOR THE GENERAL PRACTITIONER. By EDWARD E. CORNWALL, Ph.B., M.D.; Attending Physician, Williamsburgh and Norwegian Hospitals; Consulting Physician, Bethany Deaconess Hospital; Formerly Professor of Medicine, Brooklyn Post Graduate Medical School; Fellow of the American College of Physicians, etc. Price, \$1.50. New York: Rebman Company, 1917.

MANY works have been written recently regarding diseases of the heart, and this has been rendered largely necessary not only because such diseases are of great importance, but also on account of the great advances made within the past few years in methods of diagnosis. This book by Dr. Cornwall is a practical clinical treatise and is based on the latest discoveries with regard to modes of diagnosis and treatment. It may be recommended to the attention of practitioners and students.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 28, 1918.

DR. FREDERIC E. SONDERN IN THE CHAIR.

AFTER the usual order of business and the reading of the committees appointed to serve for the coming year, the treasurer, Dr. Frederic E. Sondern, read his annual report, which was followed by the report of the auditing committee. These reports were adopted by the Society.

Inaugural Address of the President.—Dr. HOWARD CANNING TAYLOR, after expressing his appreciation and gratitude for the honor conferred upon him in his election as president of one of the largest medical organizations in the country, dwelt upon the responsibility of the Society for the welfare of the community from the standpoint of public health. He stated that of all the affairs that concerned the Society the welfare of the community must come first. When they had given their service in behalf of the public welfare to the full extent of their ability, they would then be in a position to demand proper recognition of the medical profession on the part of the community. As a Society they owed certain duties to the community and to the profession and the time had arrived when they should ask themselves if they were meeting these responsibilities or whether they were simply drifting. As a Society of three thousand members he thought they should ask themselves whether they were doing a definite constructive work. As a member of the Comitia Minora he had formed an idea of the work that the Society should do. They had done much admirable work in the past. They should continue to do the work they had been doing, but they should add to that work. Obviously, with a membership of nearly three thousand members the Society was too large for deliberative work and much of this kind of work would have to be done through committees. He, therefore, advised that the interests of the Society would be better protected if most of the resolutions presented were referred to the Comitia Minora for considerations before being adopted. There were two types of complaints that came before the Comitia Minora; first, those made by a layman against a physician because of supposed wrong treatment or because of improper behavior, and, second, those complaints made by one physician against another because of alleged unprofessional conduct. In the first class of complaints the Comitia Minora had usually been able to explain a course of action that seemed wrong to a layman and to adjust the grievance satisfactorily. During the two years in which the speaker had been a member of the Comitia Minora there had been no case in which a member had needed admonition or censure; this suggested an important function of the Comitia Minora, that of acting in an advisory capacity. Another point brought out by Dr. Taylor was that if as an individual a physician could not advertise his laboratory, it was not right that a group of men should advertise a laboratory. The Comitia Minora should express its disapproval of advertising by a group of men. As it was the function of the Comitia Minora to settle disputes between physicians themselves and between physicians and patients, any plan of action that was contemplated which might involve a dispute or a difference of opinion might better be laid before the Comitia Minora for an expression of their opinion. It was their work to be helpful as advisers and not merely to discipline members. A further point that needed emphasis was that there should be closer cooperation between the Legislative Committee and the Counsel. The Counsel was in a position to know how any proposed law was going to affect the members of the Society, and it might be advisable for the Legislative Committee to seek his advice more frequently. Dr. Taylor commended the activity and efficiency of the Counsel of the Society and recommended that he be treated a little more liberally from the financial standpoint. He recommended that for a body as large as this Society it would be an advantage to have a lay executive head who should be a man familiar with

social and economic questions related to medicine, and who should devote his entire time to the affairs of the Society.

Report of Committee on Drug Addiction.—Dr. FRANK VAN FLEET, chairman of this committee, submitted this report, which was read by the secretary. The purport of the text of this report was to the effect that the present antinarcotic drug law failed to fulfill its purpose, subjected the legitimate practitioner of medicine to much inconvenience and annoyance, and should be amended.

A minority report was then presented by Dr. John Davin which reviewed the findings of the Whitney Legislative Committee and charged that the special committee had not performed the work for which it was appointed. The report charged that the committee made no competent effort. "The testimony at the hearings of the Whitney Committee shows abuses and evils within and without the medical profession. The majority report contains practically nothing specific concerning the matters for the investigation of which the committee was appointed. Events of the last year, climaxed by the Whitney hearing, permit by medical men no further ignoring of the importance of the narcotic drug addict problem and no further evasion of responsibility by our profession." The report recommended that a new special committee be appointed which would give to this problem the attention it deserved.

After a spirited discussion the majority report was adopted.

Recruiting of the Medical Reserve Officer.—Major FREDERICK T. VAN BEUREN spoke on this subject. He stated that the business of recruiting had a past, a present, and a future. Somewhere about a year ago, under the leadership of the medical member of the Advisory Commission, a Medical Section of the Council of National Defense was formed in Washington with the object of assisting the Surgeon General to secure the necessary reserves of medical officers and of co-operating in any other activities desired of him. The Central National Committee at once set about the formation of State Committees and the latter began the formation of County Committees, so that in a comparatively few months a great body of medical men were set to hunting among their professional brethren for prospective medical officers. Some hunted hard, and some did not, but the net result of their labors was that on Jan. 19, 1918, 20,861 physicians had been recommended for commission by the Surgeon General in the Medical Reserve Corps. Although the methods by which this was accomplished varied somewhat, the commonest and most successful were information and exhortation. In New York State a special medical census was taken with a view to ascertaining accurately the resources of medical personnel in the State. For that they had to thank Major Earl Connell whose initiative and persistence gave to the State a scientific classification of the entire profession which had served as a model to a number of similar undertakings. Next, a recruiting tour was undertaken for the purpose of spreading abroad the news that medical officers were needed for the army. Seven officers, assigned to active duty for the purpose, collectively visited 60 counties of the State in three weeks' time at a cost of about ten dollars for each applicant secured. The immediate result was 223 applicants for the commission accepted. Another result of this tour was that the officers who made it returned with the conviction—which later experiences had only hardened—that a form of selective draft, based on a Federal Classification of all physicians and with stated exemption, would be the most desirable, most efficient, and fairest method of securing the enormous numbers of medical officers needed for our prospective armies. It was not considered feasible by the General Committee at Washington to institute such measures at the time and the New York State Committee was directed to secure as many applicants for commissions as rapidly as possible by the individual volunteering method. The faith of the Touring Board in mass volunteering with selective draft was, however, ratified by the New York State Committee in a unanimous resolution, and permission was secured from the Central Committee to agitate for it as a future method while continuing to secure

individual volunteers in the old way. To carry out their plans concerted efforts were made to disseminate information as to the need for medical officers and to secure the acceptance of the principle of universal service among the medical men of the State. The information was disseminated by thirteen serial letters of instruction and exhortation, by hundreds of personal appeals, by thousands of letters to recent graduates of the College of Physicians and Surgeons, and of Cornell Medical College and to young physicians classed by the Medical Census as available and desirable, throughout the entire State. Many open letters, editorials, articles, and news items were published in the daily papers and medical journals. The effort to prepare for a more conservative and efficient mode of recruiting for the future took the form of a petition setting forth the advantages of universal service and selective draft, based on classification with exemption, authorized by the State committee and sent out to county committees and county medical societies, branches of the State Medical Society, and every hospital and medical school in the State. About 8000 copies were also sent to individuals. This petition actually secured the signatures of more than 10 per cent of all the physicians in the State and the movement had the approval of many leaders of the profession in civil life as well as the unofficial commendation of many officers in the medical department of the army and navy. More than 20 other State committees had expressed a belief in the justice of the principle of universal service and about a dozen of them wrote to the central committee in Washington advocating a widespread agitation for its acceptance. As the results of these and other activities 2000 physicians from New York State had joined the medical reserve corps between May 1, 1917, and January 1, 1918, and the medical profession of this State were seriously considering the desirability of a scheme of universal service whereby each man, whether in private practice, hospital, medical school, or in the army, might feel that he was doing his duty by the Government and under the Government, and might feel that others knew that he was doing it.

Up to the present time, 20,861 men had been recommended for commissions from the whole United States, of whom 2,537 were from New York State. But only 16,206 were actually in the reserve corps to-day, 1,264 having declined the commissions offered, 636 having been discharged since being commissioned, and 2,755 being still on the way from recommendation for, to actual acceptance of, commissions. Of the 2,735 recommended from our State probably not more than 2000 were today actually in the corps, and they had not done more than their duty by the first draft, while the second was soon to follow. They had, however, pretty nearly enough in numbers for the present army, although the quality might in certain instances be improved. Consequently, the rather indiscriminate previous efforts to secure the largest number possible in the shortest possible time were giving way to attempts to secure men of known desirability. Lists were being prepared of physicians of recognized ability throughout the United States as well as in this State, and the individuals on such lists were being invited by individual letter to apply for commissions.

No one knew how long this war would last or how many medical officers would be needed. If we eventually required 45,000, as Bloodgood estimated, we should have to take more than one-half the available supply, selection of the most careful and rigid description would be absolutely necessary to protect the integrity of the civil medical structure. The present volunteering system was showing its weakness by slowing up of the number of applicants, by echoes from the camps and cantonments regarding unsuitability of some of the men commissioned, by known individual injustices allowed to occur in certain hospitals, medical schools, and communities, and the formation of the Auxiliary Medical Service Corps intended to receive a large number of men who for sufficient reasons could not apply for distant duty, but who desired to serve. In closing, Dr. Van Beuren declared that mass volunteering of the entire profession with selective draft of those fittest for army service, based upon a classification with stated exemptions, was the rational system to be desired in choosing the medical officers responsible for our troops in war. Was it too much to hope that this

society and the medical profession of this State and of the other great States would soon resolve to declare their belief in universal service, in time of war, for the medical profession and for others, and would set a brave and admirable example by offering as a body, their individual services to the nation in its need?

Surgical Training at Bellevue Hospital.—Dr. JOHN HARTWELL described the course which was being given, more correctly than stated in the title, as a part of the activities of Cornell University Medical School. This was one of ten of such courses established on October 1, 1917, by the Surgeon General in various medical schools throughout the country. These courses had been organized for work by November 1. Hospitals, had been asked to give a course with the view of getting the men trained to the standard of Base Hospital 116, which was supposed to be the standard hospital on the other side. At Cornell they had been asked to give a course in the treatment of fractures. As a result of a conference with a number of the men it was decided that a course in fractures alone would be too much of a special course, so they had asked the privilege of enlarging the course so that it would include all phases of medicine applicable to a military hospital. Of the 16,000 men in the Medical Reserve Corps many had been recruited from country practice and from internal medicine, and many had had no training in a large hospital. Furthermore, there was only about one large hospital in ten at the present time that had a man who had specialized in traumatic surgery, so the idea was to start a course that would give a man an insight, as far as was possible in one month, into modern war hospital methods. They had called in all the men in the faculty who were teaching laboratory studies and the specialists in new antiseptics, particularly the chlorine group, and they had called in the bacteriologists because bacteriology had become the basis upon which the treatment of war wounds depended. Never before had bacteriology had such an application to surgery as during the past three years, as all knew who were familiar with the work of Sir Almroth Wright, Munson, Carrel, and others. It was very interesting to see the way in which the men came from active practice into the laboratory work. The first week of the course was spent almost entirely in the laboratory, and each succeeding week the laboratory work was decreased and the other lines of work increased. During the first week, in addition to the laboratory work, the men were introduced to a knowledge of the new splints and compound fractures. The last week of the course was spent in the wards of the hospital applying the principles they had been learning during the previous three weeks. They had established a course in the Carrel-Dakin method of wound treatment as taught at the Rockefeller War Demonstration Hospital. The course had started with ten members, but later they had been asked to increase it to fifteen or twenty. The first intention was to conduct the course for only three months, as the men who were giving the instruction were all busy men, the heads of departments, and were doing the work at the cost of considerable personal inconvenience and sacrifice, but these men had requested that they be permitted to continue with the work because they said that they had just gotten fairly into it and hated to give it up. The reports that came to them indicated that the medical officers appreciated these courses.

General Training at Fort Benjamin Harrison.—Capt. WATSON LAWRENCE spoke on this subject, by invitation. He told the story of his own arrival at Camp Benjamin Harrison and related his personal experiences in adapting himself to camp life. The medical camp was organized on the basis of 80 to 150 men to a company, though generally there were about 85 men in a company. Each company had two barracks, a mess hall, and a latrine to itself. The barracks were crude and rough, but supplied sufficient protection during the summer and fall, though they had not become entirely accustomed to them in the winter. On their first arrival the men who had had some experience in military affairs, or had been trained earlier in the war, were selected as sergeants and corporals, and the remainder of the new arrivals were like privates and were treated as such. The instruction of the medical men at Fort Benjamin Harrison was entirely military. The men rose at five o'clock, had one-half hour for dressing,

then had setting-up exercises. They then had breakfast, after which they made their beds and then met for a hike. There was nothing in the military routine that a man physically sound could not stand and he had seen no man thus far who was not better physically and mentally for the training. The hike lasted for an hour and they kept going steadily during that time, usually at a gait of 120 steps to the minute. After this they were allowed a few minutes in which to get a drink, and then they had drill for an hour. At eleven o'clock they had a lecture in the barracks or hall and were taught the Army Medical Paper Work. This was very complicated and he had thus far met only one man who seemed to understand it thoroughly. They were also taught equitation. Every week there was a general review of all the troops at the camp, some 4000 or 5000. On these occasions the medical men went to the general parade ground and the doctors made a creditable, showing considering that they had had no military training before. Some of the men claimed that they had not come into the army to be made soldiers and that there was no use trying to make a soldier out of a country doctor. But in spite of the complaints the military training was a good thing for them. Captain Lawrence described the meeting of Military Surgeons of America at Fort Benjamin Harrison and other diversions of camp life and spoke of the spirit of fellowship and comradeship that prevailed. He advised men going into the service not to buy an expensive equipment until they knew what they would need, and said that whatever they might need they could buy wherever they were sent. He emphasized the fact that a military training was very essential for the medical man in the army and that a physician who was thrown with military officers would feel greatly the lack of such training. In closing, he said that he had seen our new draft army and that for the benefit of any one who had doubts as to its efficiency he wanted to say that those men were the finest specimens of manhood he had ever seen, that the Plattsburg officers had gone into the work with a serious purpose, they were mostly graduates of New England universities and he was glad of an opportunity to say that it was the finest army the world had ever seen and that when it got to France we might expect great things to happen.

Training in the Neurosurgical School of New York.—Dr. CHARLES A. ELSBERG told of the work of this school which offered a course of ten weeks. He stated that most of the medical officers who came for instruction were general practitioners and knew little about neurosurgical diseases. If there was anything about which they knew very little it was about the symptoms of nervous diseases, and the symptoms of injuries to the central nervous system. Between 8 and 10 per cent of all injuries were injuries affecting the brain and spinal cord and the main nerve trunks. It was therefore important that a large number of surgeons should have a knowledge of neurological diagnosis and of the indications for treatment in injuries of the nervous system. It was a very far-sighted idea on the part of the Surgeon General to organize in a number of cities in this country neurosurgical schools for the training in this branch of surgery in which few had experience except in fractures of the skull, or an occasional injury to peripheral nerves. Neurosurgical schools had been established in Philadelphia, Chicago, St. Louis, and New York. A regular course of ten weeks was offered for a class of twenty to thirty men. Thirty to forty hours a week were given to the work. They could not, of course, make an expert neurological surgeon of a man in ten weeks—that would take ten years or longer and often even then could not be done, but the men received enough training to be able to think neurologically without the advice of a specialist in neurology, to understand what should be done from the surgical standpoint, and when they made up their minds what should be done, there were a few good neurological surgeons who were able to do the actual work. The Allies had had the experience that a large number of men had been forced to do neurosurgical work who were totally unfitted for it and as a consequence there had been some most unfortunate results. To the neurosurgical school in New York were sent not only the younger men in the profession, but a number of men with a large surgical experience. They felt that with

these older men the course should be clinical as well as theoretical. They had systematized groups of studies which were carried out as far as possible. Everything circled around the anatomical instruction given by Dr. Tilney. The surgeons considered fractures of the skull from every aspect, beginning with the mechanics and going on to a study of the results of hemorrhage, meningitis, etc., complicating fractures. They studied the operative methods, such as decompression, the methods being demonstrated and the operations being performed on the cadaver. Hitherto in the study of medicine very little attention had been paid to the actual course of the nerve fibers in the peripheral nerves. In order to do correct nerve sutures it was necessary to understand the anatomy of the distribution of the peripheral nerve fibers. Each case of injury to the peripheral nerves offered great opportunity for study. The attention of the student officers was directed particularly to this line of work. They had been most fortunate in having the assistance of almost all of the best neurologists in the city. The roster of lectures and demonstrations were made up each week, providing for six or seven hours' work daily. Dr. Elsberg presented the detailed schedule of the course which showed that special emphasis was placed on the surgical anatomy of the nerves, their clinical neurology, and clinical pathology. There was no doubt that these courses would be of the greatest benefit to the men when the war was over as well as during the war.

Training in Plastic Surgery of the Face.—Dr. ROBERT T. FRANK described the training in this branch of surgery which was being given to the medical military officers. He stated that about 20 per cent of those who survived the primary injuries of the present war had injuries of the face. For teaching the plastic repair of injuries to the face there were three schools, in addition to the one in New York, one in Philadelphia, one in Chicago, and one in St. Louis. The courses given in these schools aimed to show the principles upon which to proceed in the repair of injuries to the face. The whole course comprised 112 hours, covering a period of three weeks. Of this time 50 hours were spent in the anatomical laboratory or in the study of the surgical anatomy of the complex region of the face with that of the various sinuses. In this work there had been ready cooperation between the dentists and the medical men. Dr. Frank said that he could best show how this class of injuries was handled by following a soldier from the time he received his injury through until his treatment was completed. The plan for the care of these injuries provided a certain group of surgeons for their care at the first-aid station. If one took a common injury, as for instance one in which the whole jaw was practically torn off, to one not familiar with the treatment of these injuries the situation would look most discouraging. At the first-aid station in the case of such an injury all the tissues that were without vitality were cut away and a first-aid dressing applied. The man was then sent to the next station where the proper dental splints were applied. Then he was sent to a base hospital where the deformities were corrected. When he had finally recovered he was sent to a restoration hospital where further work might be done to lessen disfigurement as far as possible. It was surprising to see what slight deformities remained in the cases in which the injuries had been so extensive and the outlook so discouraging. Restorative plastic surgery in these cases saved the soldier much mental agony and enabled him to chew his food, to talk, and to go about his business again.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

291st Regular Meeting, Held December 7, 1917.

THE PRESIDENT, DR. GORHAM BACON, IN THE CHAIR.

The King's Evil and Its Relation to Psychotherapy.—Dr. M. ALLEN STARR read this paper. He referred to the varied and many types of treatments for the ills of mankind which had met with success for a time and later had fallen into disrepute and been partly abandoned. He called attention especially to one which demonstrated the proof of the personal element in therapeutics, namely the cure of the King's Evil by

the touch of the King. The use of this method of treatment dated back to Pyrrhus, King of Epirus, who lived 300 years before Christ. The early Christian Fathers, following the example of Christ, cured disease by the laying on of hands. In England, from 1050 to 1786, every king touched for the evil with considerable success. It was also extensively practised among the kings of France. This condition known as King's Evil was characterized by swelling of the glands of the neck, commonly called in these days scrofula. This condition arose from a variety of causes. It might be the result of a general infection as in diphtheria, measles, or scarlatina; or secondary to catarrhal conditions of the nasopharynx, adenoids or tonsillitis, or to ulcerations in the mouth, wounds in the scalp, or even lice. Tuberculosis was the most common cause of swollen glands and produced the chronic stage, with much spontaneous variation in size, and sometimes subsiding without suppuration. Hodgkin's disease caused the largest and most persistent swellings without recovery. Lastly a luetic enlargement of the glands might be mentioned which might recover spontaneously. All these conditions were formerly included in the term scrofula. While a spontaneous recovery from this symptom could occur, it was in bygone days attributed to the royal touch, just as at present many spontaneous recoveries were ascribed to methods which a scientific physician regarded with a large degree of skepticism. In these cures of the King's Evil, as in those by the miracle of Lourdes and of St. Anne de Beaupré and other like methods of cure, the element of confidence in the person to be cured is an active agent in the successful result. When it is realized that even a slight passing emotion is sufficient to change the electrical resistance in the hands to such a degree as to be measurable by a galvanometer, it cannot be denied that strong emotions, such as were inevitable in preparation for seeing the King, the excitement of the crowd, the impression made by a ritual service of some length, the actual thrill caused by contact with royalty, and the sustained expectation secured by possession of the angel or amulet, might easily set up chemical changes in the system of a stimulating and possibly beneficial character. The influence of mind on body, of hope and courage and conviction in giving strength was never to be overlooked, and the man would be a poor practitioner who did not utilize this influence in the treatment of his patients. (See also MEDICAL RECORD, December 29, 1917.)

Dr. DANA said that he thought that many of the therapeutic measures referred to by Dr. Starr had still some merit. Blood-letting had a definite position and value in treatment. Hypnotism had also a use, and on the whole had a wider range of value than psychoanalysis which often only furnished morbid interest to the doctor and was at its best suitable only for the intelligent and the not too old. Christian Science had shown that the medical profession ought to pay more attention to the personality and to the soul; osteopathy and chiropractics had shown that their practitioners could live by just paying attention to the back. Just now therapeutics was dominated by surgery and the doctor was impatient if he could not find something objective and cut it out. Dr. Dana thought there should be a special chair in medical colleges for teaching students how to behave and how to study their patient's behavior and personality.

Dr. ABBE said he was surprised to learn that Dr. Starr was inclined to attribute most of the value of the Weir Mitchell cure to Dr. Mitchell. He had thought that the method rested on a sound foundation apart from the great personality of the deviser.

Dr. GILMAN THOMPSON presented a specimen of an "Angel" loaned by the American Numismatic Society. The value of the gold was about \$1.50. It was hammered on a die and had an uneven edge. It was perforated so that it might be used as an amulet. Dr. Thompson quoted remedies and prescriptions from "Boyle's Philosophy," published in 1725, which related amusing methods of treatment of the "King's Evil."

Dr. GIBNEY said he had seen several cases in which harm had been done by chiropractors. One woman of advanced age with pains in legs had been treated by suspension and pounding with the result that after each treatment she developed spasm of the ham-string muscles. When asked why she had gone back the reply

was that she had been obliged to purchase tickets for 25 treatments on the occasion of the first visit.

Dr. STARR said he believed that all cases of actual cure by faith-healers were cases of hysteria, *i. e.* the origin of the condition was exclusively mental. We see similar cases in practice. He had had a patient paralyzed and without sensation below the waist for three years. It was an hysterical paraplegia. He hypnotized her and told her to walk, which she did. Her friends called it a miracle. She was frequently hypnotized at increasing intervals, on each occasion just before the paralysis was due to return. She was under observation four weeks. At last it was suggested during hypnosis that she was perfectly well. She had so remained. In reply to a question, he said that the "King's Evil" seemed to have been a disease of the glands of the neck. This was also called scrofula. Apparently no distinction was made between the various causes of glandular enlargement. It was known that these suppurating glands when licked by dogs caused disease in them. He said he had hoped to bring out in his paper the evolution through which medicine had gone. He had not meant to discredit all the methods of treatment mentioned. Modern Medicine had retained some methods but had discarded others shown to be unfit.

Paget's Disease.—Dr. ROBERT ABBE reported a case in which there was an hypertrophy of the horizontal plate of the upper jaw to 2½ inches. The masses protruded like two buttocks from the roof of the mouth. The general appearance was unsightly. In this case the mucoplate and the gums were stripped back and the mass chiseled and rongueured away. These cases were called Osteofibrosis or Paget's Disease. They had a typical appearance. Sometimes the jaw cases were mistaken for sarcoma. Frequently the fibula or radius was spiral, the clavicle or femora curved, or the ribs sharply bent. Thickening of the skull was practically constant. The sella turcica was normal and the brain function unimpaired. Frequently one single bone was first affected, *i. e.*, it was a "one bone disease" at first. Surgical repair was always good. As to heredity, a brother of one patient had a very advanced identical condition. The patient was therefore questioned and stated that a nephew had the same condition beginning. There had been suggested an origin from tooth socket infection. It might be due to the pineal gland but not to the hypophysis.

Dr. STARR said that a few years ago he had reported a case of so-called leontiasis ossium. Putnam of Boston had described two cases. Dr. Starr described his case under megaloccephaly in the *American Journal of the Medical Sciences*. The bones of the face had not grown as had the remainder of the skull. The patient was under observation for several years, finally developing a neuralgia due to compression of the fifth nerve at the foramen. This was before the days of x-ray. He believed the case would have shown a skull condition similar to Paget's disease.

The Abuse of Tincture of Iodine in the Operating Room.—Dr. V. P. GIBNEY reported these two cases:

CASE I.—A girl, eight years of age, was operated upon in the Hospital for Ruptured and Crippled in December, 1915, for talipes calcaneus resulting from poliomyelitis. The operation, astragalectomy, was done by the house surgeon. The lower part of the leg and the foot were freely painted with tincture of iodine, diluted one-half, immediately before the operation. At the completion of the operation care was not taken to remove the iodine with alcohol as was the custom with most operators. A full dressing was employed and over all of this plaster-of-paris was applied to maintain the foot in the desired position. During the first week there was no reaction, but at the beginning of the second week the temperature rose to 104°, and there was found a bulla on the tarsal aspect of the foot just under the plaster. The toes were swollen and very painful. The plaster-of-paris was cut down at once and there was found an extensive dermatitis extending up to the edge of the wound. Two or three of the bullæ had broken down. The wound, which had already begun to heal, became infected and bichloride dressings were used freely but without any relief. A little later it was found necessary to open the wound throughout and expose every surface of it by turning the foot

toward the outer side at a right angle with the leg. They were thus able to get through drainage and a boric acid drip was employed continuously for a month. The wounds became clean and healing began. They were able to bring the foot gradually around into the normal position about six weeks after. In the latter part of February, 1916, there was noted a large ulcer on the inner side of the foot. The foot had been fully restored to the desired position, but the wounds were not healed until April 13, 1916. A brace was then applied and the patient discharged May 11, practically cured. The patient had been traced and at the Clinic they were delighted to find the foot in good position, very useful, and having a small range of motion, which enabled the patient to walk with scarcely a limp. The end result, therefore, was excellent.

CASE II.—A boy, eight years of age, was admitted to the Hospital for dangle foot on the right side, and slight calcaneus on the left. This was early in December, 1917, and on Dec. 10 an astragalectomy was done with the usual iodine preparation and with the usual dressing and plaster-of-paris, but precaution was not taken to remove the iodine from the foot, especially between the toes. All went well for a week, but then the temperature began to rise and one could see a large bulla under the plaster-of-paris on the dorsum of the foot. On removing the dressing dermatitis was present, but had not quite extended up to the wound and by timely interference this foot was saved from a similar disaster. This child made a good recovery, but there was still a superficial cicatrix on the dorsum of the foot and on the upper third of the leg.

In the earlier days of the use of iodine a stronger solution was employed and the area covered was not nearly so great as at present. Now we used from 2½ to 5 per cent. and usually this strength was enough to produce a dermatitis on a sensitive skin. The surgeon in the operating room and the operating room nurse or her assistant did not know whether the limb was particularly sensitive to iodine or not; it was, therefore, incumbent upon the operator and his assistants to see that the iodine which had been placed on the limb had been thoroughly removed before a full dressing was applied, and especially the one over which plaster-of-paris must go. It was a current report that iodine, as an aseptic, had been discontinued in some of the operating rooms, although it was regarded as one of the best methods of preparing the skin for operation. This communication was not, however, to condemn its use, but merely to call attention to its abuse.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

REAGENTS AND REACTIONS. By EDGARDO TOGNOLI, M.D. 227 pages. Price, \$2.00. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

THERAPEUTIC IMMUNIZATION, THEORY AND PRACTICE. By W. M. CROFTON, M.D. 224 pages. Price, \$2.50 net. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

TREATISE ON APPLIED ANALYTICAL CHEMISTRY, METHODS AND STANDARDS. By Prof. VITTORIO VILLAVECCHIA. Vol. 1. 475 pages. Illustrated. Price, \$6.00. Published by P. Blakiston's Son & Co., Philadelphia.

HYSTERIE-PITHIATISME ET TROUBLES NERVEUX, D'ORDRE REFLEXE. Par J. BABINSKI et J. FROMONT. Second Edition. 295 pages. Illustrated. Price, 4 francs. Published by Masson & Cie, Paris.

TROUBLES LOCOMOTEURS, CONSECUTIFS AUX PLAIES DE GUERRE. Par AUG. BROCA. 155 pages. Illustrated. Price, 4 francs. Published by Masson & Cie, Paris.

LA PROTHÈSE DU MEMBRE INFÉRIEUR. Par Le Dr. F. MARTIN. 101 pages. Illustrated. Price, 5 francs. Published by Masson & Cie, Paris.

TYPHOID FEVER. By FREDERICK P. GAY. 286 pages. Price, \$2.50. Published by The Macmillan Company, New York.

Therapeutic Hints.

Intestinal Indigestion.—A careful study, investigation, and regulation of the diet is necessary. Ferments given with the meals, or predigested food for a certain length of time, gives relief. Pancreatin, given in 5 to 10-grain doses with bicarbonate of soda, and alkaline mineral waters are advisable when the urine is concentrated and acid. Constant abdominal distress may be due to a growth or duodenal ulcer which demands surgical relief. When much flatulence is present the following formula may be prescribed:

R Acidi nitrici diluti...f5ij vel 5iij (80-12.0)

Tinct. cardamomi compositæ,

f5vj (180.0) — M

Sig.—Dessertspoonful (8.0) in water four times a day.

Sometimes flatulence of the large bowel associated with atony of the muscular coats of the gut is present. Then the following proves beneficial:

R Asafœtidæ gr. xl (2.6)

Extracti nucis vomicæ...gr. iv (0.25)

Extracti physostigmatis...gr. iii (0.20)

Oleoresini capsici.....ꝑx (0.60) —M

Ft. pilulæ No. xx.

Sig.—One pill three times a day, two hours after meals.

Or,

R Tinct. belladonnæ foliorum...f5iij (12.0)

Tinct. physostigmatis.....f5iiss (6.0)

Spiritus camphoræ...q.s. ad f5iij (90.0) —M

Sig.—Teaspoonful (4.0) two hours after meals whenever needed.

Abdominal massage is valuable in the treatment of this condition. The patient can procure results by slowly rolling a three-pound cannon ball over the course of the colon, to urge on the intestinal contents and cause secretion. A roller electrode applied with the rapidly interrupted current from a faradic apparatus will strengthen the intestines and produce the above result.

When intestinal indigestion results from lien-tery the treatment is different and effort must be made to increase the action of the glands of the intestinal wall. Often minute doses of mercury bichloride or podophyllin, 1/60 to 1/40 grain (0.001—0.0015) of the first or second respectively. If the liver is torpid the following may be used:

R Ac. nitrohydrochlor. (not dil)...f5ss (2.0)

Tr. gentianæ comp...q.s. ad f5vj (180.0)

M. Sig.—Dessertspoonful (8.0) every four hours or after meals, in water.—Hare, in *Practical Therapeutics*.

Acne.—Hare advises the use of the following formula in cases of young women who suffer from this condition, especially at the menstrual periods:

R Sulphuris præcipitati.....5j (4.0)

Adipis lanæ hydrosi.....5j (30.0)

M. Sig.—Apply once or twice daily.—Practical Therapeutics.

Heartburn.—

R Magnesii sulphatis 5i

Tr. hyoscyami ꝑxv

Aquæ 5ii

M. et ft. haustus.

Sig.: Take three times a day after meals.—Aitken.

THE PROBLEM THAT MENTAL DISORDERS PRESENT TO THE MEDICAL PROFES- SION, AND THE PROFESSION'S RESPONSIBILITY.

By WALTER B. JAMES, M.D.,

NEW YORK.

PERHAPS, when one whose professional activities have been limited to Internal Medicine trespasses even upon the edges of the field of Psychiatry, an explanation of his temerity would be in order. Membership on "The State Hospital Development Commission" has in the past eight months required of me a visit to all the State Hospitals for the Insane and to all the State Institutions for the care of the Feeble-minded and Epileptic, and has crystallized certain impressions, heretofore nebulous, on the subject of to-night's discussion.

The Commission was created by act of Legislature last April and is required to study the subject of insanity in New York State, estimate the capacity of the present hospitals, determine the best method of caring for these dependents from the point of view of the patients and of the rest of the State, to formulate a plan for meeting the present overcrowding as well as a plan to meet the conditions that will exist in the coming ten years, and to devise a policy for meeting the problem of feeble-mindedness. All of which evidently constitutes a labor of no small difficulty and complexity.

Among the many interesting collateral questions that have been suggested is, why is the medical profession in general, that is, all but the neurologists and psychiatrists, so little interested in and so little informed about mental disorders.

It is only necessary to look at the more than 39,000 insane cared for by New York State in the public hospitals, to note the little that is known about their maladies and their origin, to see the inadequate efforts that are being made to understand the causes of their insanity, and the little that is being done for their treatment, as compared with what is being done for patients ill of medical and surgical diseases, to make us realize that in this era of the history of the world and of science there is something wrong somewhere.

Perhaps it may be fair, for our present purpose, to divide all the diseases that now and always will afflict mankind, and using disease in its very broad sense, into three groups—Physical disease, Mental disease, and Moral disease or misbehaviour. Originally they were viewed rather collectively, and were regarded alike as being beyond man's power to mate-

rially modify or prevent and so, as witness the Book of Job, among the loftiest virtues and meriting the highest reward was patient submission.

To-day Job's neighbors would insist upon an inquiry by the State Board of Animal Industry into the loss of his cattle, for the malady might be catching, and his boils would be treated by a staphylococcus vaccine. If he insisted upon keeping his troubles, it might result in his commitment to a hospital for the insane. This illustrates the change that has taken place in the world's point of view of physical disease.

Mental and moral disease, we still see much as Job saw them, but perhaps we are merely waiting for a change like that which in a comparatively few years has taken place in our knowledge of diseases of the body, and our attitude towards them.

On October 1, 1917, the number of insane confined in Institutions, that is, legally committed in this State, was 39,404. As the number is increasing we may fairly call it in round numbers 40,000.

This means that there are in the United States about 400,000 insane who either are or ought to be confined in asylums.

The number of feeble-minded roughly equals the insane so that the two groups together number about 800,000.

As a good many persons are cared for in their families and as many also are not confined, who were better so, it is fair to assume that the number of actually insane and the number of actually feeble-minded is probably not far from a million.

If we assume as seems probable that there is an equal number of persons suffering from some milder form of mental disorder, it seems fair to assume that there are in the United States not far from two million persons who are mentally sick.

If we compare these figures with those of other important maladies, as tuberculosis, it becomes evident that mental disorders constitute one of the most important and serious of all the disease groups.

The attitude of the public towards insanity is entirely different from that towards physical maladies. There is a sense of mystery and a feeling of awe and a desire to put these patients away, and indeed it is not long since there was a feeling of some culpability upon their part and which resulted in confining them with criminals.

The public still thinks of the insane in terms of the harm they may do, as witness the violent opposition to building hospitals for them in any neighborhood. Yet it is infinitely rare for an escaped lunatic to do anyone bodily harm, and with modern methods of caring for them escapes are far from infrequent.

Hopelessness on the part of the laity in the pres-

ence of any mental aberration is only natural, when it is shared by and generally originates with the medical profession, very few of whom are capable of distinguishing the hopeless disorders from those whose prognosis is relatively good.

Sometimes one wonders whether the psychiatrists have not surrounded their own special field with an entanglement of difficult words and obscure and bewildering phraseology to describe what are after all rather simple phenomena, and whether this does not discourage efforts at familiarity on the part of other physicians.

This is not peculiar to them, but is met with in many men of science. I believe there is a well known and useful treatise on ornithology in which the author, meaning that "Pigeons always walk, they never hop," says "The progression of the Columbae is always ambulant, never saltatorial." Possibly verbal obscurantism may have something to do with the profession's avoidance of writings on psychiatry. But probably the principal reason for the indifference of the profession is the scanty attention paid to this department of medicine in the medical schools, and the fact that often the exercises in psychiatry in addition to being scanty are optional and hence obviously not necessary to the education of the accomplished physician.

There are under commitment in New York State Institutions for the Insane more than 20,000 cases of dementia praecox, the majority in the advanced stage and constituting one of the most serious and discouraging of all medical problems. To-day we know that this disease manifests itself generally early in life and by insidious and obscure symptoms, and while treatment is far from having reached an effective stage, nevertheless we already know that much can be done towards ameliorating the condition if it is recognized in time, and there is fair reason for hoping that some day physicians will prevent it, or at least, be able to check its progress.

It is impossible to view what has been done already for the improvement of the condition of many of the worst cases of this disease by systematic training as carried out, for example, by Dr. Howard in the Rochester State Hospital without being heartened as to the possibility of a considerable measure of control at least being attained were the medical profession to really apply its collective mind to the problem. Did you ever realize that almost every one of these cases in its early stages passed through the hands of a family practitioner of medicine, who probably entirely failed to recognize or even suspect its existence, and who very likely had never heard of the disease?

In New York State many well educated physicians are unaware of the existence of the State Hospital Commission and of the State Hospitals for the care of the insane. They have never taken note of the problem presented by insanity. Comparatively few physicians know that at a cost of more than \$10,000,000 a year the State provides admirably conducted institutions, hospitals for the care and treatment of upwards of 38,000 insane and administered by a large corps of physicians.

This apathy on the part of the profession probably belongs peculiarly to the present generation, and is to a great extent the result of the very rapid development of the science of medicine, which with-

in a brief space of time has so widened its limits as to make it impossible for any one mind to grasp it all.

Another reason is the preponderance of time and interest in the schools of medicine given to the study of structure in comparison to that given to the study of function. It is pathetic, for instance, to see how much time is devoted in the departments of anatomy, physiology, and neurology to the gross and minute anatomy of the brain and how little time is given to the study of its function and that chiefly as an organ of conduction. It is interesting to see the time and thought that are given to the minute and definite localization of a small apoplexy in a parent, and for which nothing can be done beyond nursing, while a mild mental aberration in a son or daughter is passed over lightly or disregarded entirely. Perhaps one reason for this is that the former is very much simpler and easier than the latter, and makes a more interesting autopsy. The localization of lesions with a verification or otherwise at post mortem has many of the characteristics and charms of an exciting game of chance. This perhaps has something to do with its popularity, though, of course, occasionally it results in disclosing an operable lesion.

Thirty years ago the student of medicine absorbed in the microscopic study of the kidney, liver, lungs, etc., occupied with tangible physical changes, resented being called upon to study the intangible subtle changes in temperament and intelligence that indicate oncoming mental disease. The same condition exists to-day, though probably to a lesser extent. The responsibility for all this rests I am afraid with our profession. We have fallen in passively with the view of the general public, that disorders of the body and disorders of the mind belong essentially in different categories, that the one are susceptible of study, complete understanding, and often of amelioration or cure, but the other not.

Mental disease, however, has remained where it was and perhaps by reason of the difficulties connected with its study it has received a comparatively small portion of the impetus of scientific research. The figures that I gave a little while ago suggest that in its cost to the community in money, in impairment of efficiency, and in distress, mental disease compares very favorably with tuberculosis.

But compare what is being done by the scientific world towards the solution of the problem of tuberculosis with what is being done in mental disease; every State, every large city, and most indeed of the smaller ones, and many counties, have their tuberculosis societies, made up not only of professional but lay membership. Voluntary contributions are obtained, State and local public aid is secured, laboratories are built, foci of intensive study are springing up on every side, and the energies of the public as well as of the profession are bent upon solving this problem. When we come to look at mental disease from the same point of view, we find in the United States a pathetic little group of societies devoted to the study of psychiatric problems; we find very few psychiatric laboratories; we find an output—the result of research, which is insignificant as compared with the output in any one of the other fields of medicine.

Nevertheless the importance of mind in relation

to the problems of the rest of the body is universally admitted and the attempt to practise medicine without either consciously or unconsciously considering the importance of the mental factors would mean disaster and ill success.

What we need in medicine is, first, that the problems of the mind should receive more attention at the hands of teachers. For admission to the higher grade medical schools we now require a knowledge of chemistry, physics, biology, or what might be called a study of the laws of the normal body.

We should require an equally good grounding in psychology or the science of the activity of the mind.

The importance of the mind in disease, which is occasionally referred to in the medical schools, but always as a side issue, should be emphasized by a larger number of hours and every medical student should be required to have a definite amount of practical experience in institutions for the insane and should be examined upon this. I am aware that a certain amount of this is required now but it should be trebled or quadrupled. The hopeful outlook for research into the problems of psychiatry should be emphasized, for only by recruiting a number of men devoting their lives to the study of these problems can we hope to achieve all the progress possible and to realize what lies open before us.

It is unfortunate that psychiatry has always been an appendage to, a sort of a by-product of, neurology, and by a natural process, a following of the line of least resistance, the major part of the energy of the specialist has been given to neurology—only what was left over going into psychiatry. There is really not much more reason for attaching psychiatry to neurology than to any other department of medicine. There is some ground for believing that it were better attached to Internal Medicine. Perhaps a fair index of the interest in any department of medicine is the number of societies devoted to it and the number of laboratories engaged in research in it. Judged by this standard, the interest in mental disorders as compared with other disease must, in this country be judged to be very small. It is, however, growing and the number of medical and semimedical books on psychiatry that are being published indicates an increasing public and medical interest in this branch.

Surely as a field for research mental disease offers much attraction. In the first place much of it is almost virgin soil, which is always alluring. Moreover, the exciting cause of much insanity is known.

In 1915, of all admissions to the New York State Hospitals, in 55.6 per cent. the exciting cause of the trouble was known, and among these cases in 31.7 per cent. the cause was such as to suggest great hopefulness of ultimately finding a means of prevention, or cure.

There are many points of resemblance between the problems presented by insanity and by tuberculosis. It is not very long since the satisfactory solution of the problem was considered as hopeless in one as in the other and from the point of view of therapeutics they were equally discouraging. In tuberculosis we have long known that two elements were necessary for the development of the malady, a suitable soil, that is a predisposition, and an immediately causative agent, the tubercle bacillus.

In mental disease we are beginning to see the existence of two similar elements, and the development of the concept of the psychopathic temperament is one of the encouraging things in modern medicine. For instance, among the admissions to our State hospitals in 1915 in over 2 per cent. the disease followed the death of a near relative. In over 2 per cent. it followed the loss of property.

By a more complete understanding of the tuberculous predisposition and of the nature and behavior and the chemistry and biology of the tubercle bacillus, we are constantly strengthening our forces of prevention and treatment in this disease. May we not hope that similar zeal in studying the elements that enter into the predisposition to insanity may some day lead to equally gratifying results?

A comparatively recent and logical development of the therapeutics of tuberculosis is the preventorium; an institution wisely designed on the ground of modern science, where young people who show a tendency toward or a predisposition to tuberculosis, may have their bodies trained back into a state of normal resistance to the infection to which we must all perforce be from time to time exposed. This predisposition can today be recognized with fair certainty. Is it too much to expect that a more enlightened medical profession than ours, operating in a more enlightened public, will recognize the first subtle manifestations of the psychopathic temperament, and by similar methods of mental training lead the individual back gradually toward a normal plane of mental life, having reached which he will resist as normal men and women do "The slings and arrows of outrageous fortune," and go unscathed through the attacks to which his nervous system must of necessity be a target in this troubled world?

I am aware that wise physicians do in some measure aim at such methods in a few cases, but as yet the profession has no definite plan for meeting such early cases of predisposition to mental disease. Perhaps some day we shall see psychopathic preventoria as we now see them for tuberculosis.

Whatever may be the final fate of psychoanalysis, as we now know it, and I am far from regarding myself competent to express an opinion upon this point, nevertheless we must admit that Freud in any case will have rendered a distinct and valuable service to modern medicine by suggesting another way of analyzing mental problems. Although his way may possibly be abandoned as useless or give place to a better one, none the less will he have been a leader along a path upon which leaders with original ideas have been indeed too few. So that in any case medicine will be in his debt.

Finally it seems, first, that the problem of mental disorders offers no insuperable obstacle to its satisfactory solution, and that such solution is to be found through the awakened interest of the entire profession and through the continued and patient application of such scientific methods as are in process of solving or have already solved some of the most puzzling riddles of the ages. As a step toward this the State Hospital Development Commission is recommending that the Board of Regents take such steps as may be necessary to secure in all the medical colleges of the State an amount of time and interest for the disorders of the mind adequate to the subject's importance.

It is interesting to note that in psychiatry as in some other directions, the urgent war needs have caused a more intensive study of the subject than has been made before and with the promise of good results, not only in the war itself but for science and for all time. It is possible that one of the ultimate benefits to mankind from this melancholy situation will be the impulse given to the study of mental disorders and the advance in our knowledge of them that would have been hard to arrive at under peace conditions. In my summer's study of the State hospitals, it has been my good fortune to spend many nights with the medical superintendents and staffs in their comfortable quarters and I have been struck with the attractiveness of the career that these hospitals offer to ambitious young medical men, and this I confess is quite different from what I had expected. The opportunities for research are unexcelled; the interest of the subject is absorbing and the facilities that are offered to ambitious young men are unsurpassed, and from a material point of view as well these positions are far from unattractive. If these advantages were more widely known throughout the profession, I believe that positions in these hospitals would be in great demand.

Finally the outlook for advancement in our knowledge of the collateral and closely related field which I mentioned at the beginning of this paper—the field of moral disorders or disorders of behavior—is brighter than it has ever been. There are certain indications that a scientific study of crime is beginning to be taken up along the same lines that have guided medicine in its contest with disease. The study of the mentality of juvenile delinquents which has become more and more common in our courts, the general recognition of the value of an institution such as the Juvenile Detention Home in Chicago, and the present intensive study of the admissions to Sing Sing from the point of view of psychiatry by Dr. Bernard Glueck, all point to the awakening of a keener sense of responsibility for these various morbid conditions on the part of the public, and perhaps the day is not far distant when the torch which has been lighted by those who are responsible for the research into physical disease and which has already produced many benefits to mankind, will light up as well the dark places in the allied fields of mental and moral disorder and help us toward what is after all the only logical goal, the approach to the irreducible minimum of human disease, whether it be physical, mental, or moral.

Almost a year spent in the close personal study of mental disease in this State has left me filled with a spirit of optimism, and confident that some day this problem will be solved, as many other apparently hopeless medical problems have been solved, and that this solution will be hastened by interest, confidence, and cooperation on the part of the whole of our profession.

7 EAST 70TH STREET.

Adrenalin in Iodism.—According to Milian a man who was taking an intensive iodide of potassium cure and who became badly iodized was promptly benefited by the administration of adrenalin. His inference was that in severe iodism adrenalin insufficiency is set up.—*Paris Médical*.

"EYES OF YOUTH":

A DRAMA OF PAST INFLUENCES AND FUTURE POSSIBILITIES.

BY SMITH ELY JELLIFFE, M.D.,

AND

LOUISE BRINK, A.B.,

NEW YORK.

"THERE is no past or future in time as in space. Each stretches to eternity." So far the Indian sage, the Yogi of this drama, has pointed out the littleness of the present moment of action amid the resistlessness of the entire onward movement which is life. A great quiet sea, yet heaving beneath the calm surface with the whole of gathered experience, such is the past behind each individual. Before loom the impenetrable mists of the unbounded future. The affairs of each moment are no more than a tiny point of rock emerging where the ever-increasing ocean of the past pours its influence over into the instant that breaks at once toward the eluding future. The moment has already joined the past, the unknown future is still ahead, the effort to reach it is continued. Our feet touch the point which is the present moment and it is gone; we are beyond, leaping to the next point of time and experience. Vivid, clear, effulgent with an unknown glow, each momentary halting place is such a small and yet concentrated instant of experience, that we are driven bounding to the next poising place, and still we recoil before the thick mist stretching away before.

Whence comes the glow that warms and delights and inspires this moment so richly filled even as it takes flight? It streams ahead also until the heavy fogs of the future grow warm and radiant with hope and promise or lurid with a deeper, darker play of color within the gloom. It is not strange that man has reached out in every conceivable way to understand the mystery before him, and though he has paid less conscious attention to that behind, has sought nevertheless vaguely to define the influence which pressed upon him from this immeasurable past. He is ceaselessly impelled onward, ruthlessly hurled forward to know only when his path has been taken that it was not of the light. Why then should each instant of choice be so laden with richness of color and tone that present and future alike reveal themselves only to conceal themselves the more? What is the mystery that dissolves itself into so many elements of pleasure and pain, desire and effort, only to perplex and bewilder?

Man's first impulse was to explain it as of some power outside himself, mostly malicious, which came and went upon him according to its own caprice. Or as he felt the force of his own desire and its feeble antagonism to all that pressed upon his life, he conceived a sense of sin toward which the external powers assumed an attitude of punishment. This has not satisfied man, it does not today, as a sufficient interpretation of cause and effect in regard to the mysterious interdependence of present power and past influence and future possibilities of immeasurable good or ill.

Science has searched until it found cause and effect in the external world, and thus released man from his burden of haunting powers in that realm.

The world within remains however to most unfathomable, inexplicable, and still holds thought and vision bound. It is not even called the world within. The effort of the human mind to master the spell of its overwhelming power has always led man to attempt to get around to the outside of it, where he could view it objectively. His ignorance however and the helplessness which this incurs have prevented a clear scientific objectifying of the phenomena as they really are, and have led man to juggle with these things, deceive himself and misconstrue them still as forces and events without himself. He has externally projected his own inner life, unknown to himself, in order to get a better view of it, and thus has only continued to misinterpret and fail of the truth. Partly he has saved himself the keener but perhaps more actually effective agony of self-recognition and self-knowledge, which would have given him a better and more earnest control of inner as well as outer conditions.

This projection of the subjective beyond himself has nevertheless been necessary to his weakness and his slow mode of evolution, growth and the mastery of self and environment, toward which he has been able to make only gradual progress. Partly on the other hand he has, by this method of blinding and defending himself, made the way a slower and more ineffectual one. Moreover in the curious way that satisfies the contradictions of human feeling or affectivity, he has enjoyed the company of the specters he has conjured forth as responsible for these things of his destiny. His innate indolence has moreover taken refuge in them from the straightforward endeavor with which otherwise he must have attacked reality, to win from it his own progress and to utilize it for the progress of the race to which he belongs.

All this misinterpretation, ignorance in the face of the forces playing within and through man, has set his energies so at cross purposes and produced so much social confusion as well as individual pain and suffering, that many have grown impatient with this ancient attitude. Some in sickness and despair, others with a vision cleared and quickened by sympathetic touch with this need of the world, have dared to peer into the mysteries which well up around the human individual and to seek disentanglement of the elements playing there. They would bring them into a light of explanation and interpretation that some control may result. The sickness and despair, and the sympathetic aid too, lie, to be sure, even behind the effort to project them without and seek to understand them thus. This however only removes each factor from the ocean of intermingled elements to which it belongs, and therefore it is neither recognized for what it really is nor brought into control. It explains neither the boundless roll of influence which sweeps into each life, nor does it throw any light within the thick veil of the future.

The scientist, however, who would also understand this internal work and turn an analytical light upon the profound reality of all this mystery, or the helpless victim who craves a fearless knowledge, has been preceded by the artist whose intuition carries him into the heart of these things. Often his conscious intellectual thought has been

hardly aware of the things that he saw and yet his power of intuition and his skill were such that he could present them acceptably to the same intuitive appreciation and thus the help of other struggling souls. The dramatist with his ready appeal to a public mind, which unconsciously or consciously seeks behind its amusement some deeper and more lasting help, has been one of the chief artistic servants here. Yet he too, in his own partial intellectual blindness and also to meet the long obscured understanding of the people, has resort to the current forms of thought and expression. That which perhaps he sees much more truly must still make its appeal couched in objective phrases and in persons and events which still represent the projecting tendency of the subjective mind. He must speak in terms of the external world. Such indeed is the limitation of the means of communication from one individual to another, the intellectual limitation through which greater subjective fluid things must be expressed.

He nevertheless points the way fearlessly into the profound underlying truths. His truer meanings are those which in another way become clear to the analyst, who through close application to the inner thoughts and feelings of the emotional life, of the subjective personality, has come to know the reality and the strength of such subjective life, which has filled the ocean of past experience with the influences out of which mysteries arise. These become known largely through clinical experience, where the souls made sick by the struggle and the uncertainty and the buffeting of the sea of mystery and power come to bring their inner experiences and seek for analysis and adjustment. Such close intercourse with this subjective world gives knowledge of it and understanding of it. It makes one clear visioned also to understand in the artist's presentation certain indications and expressions of the actual truth under his artistic and superficially objective setting forth of these inner realities.

The analyst therefore recognizes in the artistic production something which will touch, even half unaware, the difficulties of those who labor to know themselves in the power of the mysteries. For those who in fear or desire would know the future before them, there is to his insight a better way pointed out to them. More effectual than a knowledge of just what the future may be is a mastery of it through themselves and in meeting it fearlessly and efficiently, whatever it may be. The analyst finds in the drama an opportunity for the awakening also through the artistic appeal of those who walk calmly or evasively content to leave things as they are and deaf to the call for help in universal struggle with these powers. He recognizes opportunity also for clearer understanding of his own work in answering this call, here where these things are presented in the form that subtly touches and releases the truth of this reality even while it entertains.

"Eyes of Youth" is one of those dramas which speaks a deeper language than that which appeals first to the conventional moralist. The serious-minded theater-goer or the lighter-hearted pleasure-seeker may draw certain very obvious lessons for thought from the cleverly presented "episodes." They present such various possibilities as might

offer themselves to the opening life of a talented girl. Yet each contains its bitter, very bitter draught, and their contemplation wins every one to the value of the simple choice of the path of simplicity of desire. Any number of platitudes might crowd about the suggested possibilities and the satisfactory outcome which wipes clean the slate in the end.

The drama is however far more profound than this. In the reality of life the visions are not so easily expunged. The simplicity of the ending is only one of those balancing moments of the present, behind which lies all the influence of the past and before which still looms the thick obscurity of the future. Here stands the heroine upon one of the glittering points of the Now, yearning before this great future and longing to know whither she shall walk to fulfill its best purpose for her. She can only flutteringly guess at the meaning to her young life of the commendation and the promise of her music master. She is however equally staunch to a sense of duty impressed upon her soul by years of training and discipline. Before her open out still other ways of seeming advantage, opulence and comfort on the one hand, the freedom of young love on the other.

No one of these paths nor any other is however free for her, because something in her inmost self determines events upon any of these pathways. This it is which confuses choice and makes the uncertainty in knowing what is best to seek. Unaware of this, yet feeling her helplessness, she takes refuge where human thought has always found escape from the burden and terror of recognizing and acknowledging the forces which lie within to determine each life and its course. The dark quiet form of the Hindu throws out in objective relief her groping within herself after the determined course which shall lead her. There is the mystery and remoteness of his world as well as the strangeness of his philosophy of another land and time to link him with the unfathomable mysteries within. Besides she can actually hold in her hands the crystal ball that burns with mystic splendor. Touching it, grasping it she is close, in her concentration upon it, to the ocean of unknown forces streaming up in fact through her own life, forces which shape themselves into wish and throw themselves forward into the future course. Yet clasping the unyielding glass she can sufficiently objectify the intangible strength of all this mystery to look upon it apart from herself and examine the ways she would take.

For after all what is it but her wish which stirs itself, which presents such a complexity of events upon her pathway, even those which produce confusion among themselves? "How could I," she questions in one of the pauses among these pictured events, "have seen it otherwise? Could I have wished it?"

The confusion of impulse and desire within her, the multiplicity of form and possibility in which her inner wish presents itself to her limited conscious vision, demand some objectifying aid. She is ready, as man has always been, to seize such external forms which circumstance throws into her way. Yet this process, the very cunning of the unconscious wish thus to gain access to her rea-

soning thought, deceives her that it may thus relieve her of any overwhelming sense of responsibility for the creation of such pathways of events as are outlined there. There is a censor that stands out in public gaze, working upon each individual in the form of his or her cultural ideals and the restraints and restrictions thrown out by the society in which he or she moves.

Few are bold or brave enough, nor are they sufficiently skilled in a fearless self-mastery to recognize the mysterious possibilities of action and the events that do take place, as prepared and determined within themselves, and finally given forth with all the color and vitality of the unconscious secret wish. This indeed it is which has set man to calling in the aid of demons first, kinder, wiser spirits later on, gods and devils, then all the continued mysticism of hallucination to satisfy his demand for cause even while it enabled him to fling away all personal responsibility. At the best it has kept him humbly loyal and trusting toward a beneficent divine Spirit of good. But he has shrunk from a more resolute self-control through self-knowledge. He has shunned the acknowledgment of a stern and hard reality, one beset with dangers to his own spirit but best met and attacked by a knowledge of these things as they are in the heart of man, or as the very inner man, his inherent energy, his creative self, acts and reacts upon this reality.

Certain phenomena, mysteriously called "psychic," as if the psychic were a thing apart or unusual to life, seem to some to give him access to a special form of mysticism in which his projections take shape and appearance out of his dominant wishes, hallucinations half in the dark, whisperings of a world of spirits visible to some privileged or specially qualified ones, under peculiar conditions and special circumstances and states of mind.

Others have seen in hypnotic phenomena, automatic writing, crystal gazing, strange revelations which were not of the ordinary clear light of day. Wonder and fear have arisen as if again there were something outside the self playing upon it, or something which certain gifted selves could appropriate peculiarly for themselves and for others. To any or all of these things the Indian Yogi, with his soft air of mystery, his cautious, gentle manner steeped in the ancient introspective philosophy of the Orient, has constituted a most suitable agent. Even the uniform grayness of his garments is suggestive of the calm of death and complete repose, where questions and problems of reality and its perplexing need for choice are stilled in release from all personal endeavor. The background his presence gives is strangely suited for dark mystery. His own brooding acquaintance with the inner subjective things, though he too has still his external terms for them, makes him the bearer of messages from the mystic and ascribes to him the power to penetrate the hidden things of the future. His exaltation of sentiment at the same time both stimulates to a truly spiritual purpose and leads to an idealization of the mystical external powers. For by these man has both projected his progressive ideals through the powers upon which he leaned, even while throwing upon them the responsibility and need for endeavor

which should have been his own. Thus he has both made progress and limited that progress at the same time, making his way a slow and tortuous one.

Gina Ashling, vibrant in her inmost soul with the possibilities and the wish impulses which were harbored within her, could not have tolerated the sudden naked revelation of these before herself. She is overwhelmed when through concentration upon the seemingly mystic object in her hands her gaze penetrates deeper and deeper into the abysses that lie concealed. To her they are only the dizzying, bounding or despairing possibilities of the future. And as such they seem only to come from without, whatever may be her share of conscious choice in following them. Also they are handed to her as visions through the medium of the kindly sympathetic and seemingly wise and noble Yogi. Thus alone has she courage to face them not only, but to acknowledge them as within the scope of her life and range of her experience.

For hers is the immediate inheritance and cultural training of a parentage and social environment which expected and had prepared a careful pathway of circumspection, unselfish service, a devotion, even though a too narrowed one, to the superficial well being of others. Duty loomed large and smote with a note of the New England conscience upon the girl sensitive by nature and training. Yet even duty had become very befogging because it was based upon the limited selfishness of those who surrounded her, and was hedged in by their more immediate needs. Duty at the sacrifice of the normal impulses and functions of life, she has to learn, cannot bring real values to herself or her family.

Behind all this nevertheless lay a deeper inheritance, which reached much further back into the slow development of the girl's full and rich young nature. The elements within it made demands which swept far beyond these narrowed ones which her devoted and dependent family, or her numerous lovers presented to her. Even the prospect of self-realization through the career which thrust its likelihood before her was infused with a power and complexity of impulses and desires which had been gathering strength throughout all the preparation of this individual psychical life.

This heritage had slowly accrued to her through the long line of women stretching away far beyond her immediate ancestors. This ocean of the past which rolls unceasingly behind the present moment of each life contains a record of all the past. "All that we have felt, thought, and willed is there leaning over the present." So has said one of our modern thinkers. This explains the measurelessness of the past behind the present. It affirms the source of the glow which spreads through this present and passes over to color the future for good or for ill. "All we have felt, thought, and willed"—and feeling has kept its full value. Sometimes we have learned a new and better discharge for it, but in its discharge it stores up yet richer affect, the result again of the new experience. Much of it has been denied discharge and has not found transformation into the more cultural ways of expression that the race has learned, so that beaten down, it is rebelliously active there in the unconscious life.

At best traces of its passage over into action, the further emotional response which resulted when such action took place, some remaining imprisoned, denied desire, and the pleasure of phantasy which easily surrounds this, all are there to produce and maintain an effulgence which burns into present and future and also to keep alive and stimulate to new and higher effort wishes which belong to the long history and prehistory of modern life.

This it is which explains the great outpouring of possibilities in the three visions which Gina obtained into the future. No more than the world acknowledges the content of its dreams, which come in such strange, grotesque, inexplicable form, as arising out of wishes, could her conscious thought recognize these startling apparitions of the future possibility in all their diversity, as expressions of her own desire. Yet the wish is within her inmost nature, the long train of unsatisfied or half satisfied desires stealing upon her individual life out of the far depths of the past. She with each individual has much in common with such a line of ancestors reaching back through the ages when wishes took to themselves progressing ways of expression and gratification, which gradually built up life's complexity and entangled its interactions.

These wishes could not always be granted or fulfilled in their direct form because that was crude, too self-seeking and asocial as society grew to a greater culture involving the higher development of the greater number. Elemental desire, informed with the energy of life, was no less alive and forceful but it had to seek less egoistic ways of fulfillment, losing therefore often the immediate pleasure for the sake of a more remote cultural gain and satisfaction. These primitive wishes and their successors, which have however also gradually yielded to cultural demands, remain deep within the heart of every man and woman. They remain to irradiate the later higher attainments of life, spiritualizations, intellectualizations, with an earthy glow that keeps the life true to the nourishing soil at the bottom from which it sprang. Yet in the light of higher attainments and the restrictions they put upon each individual life they dare not stand in the clear light of conscious recognition except in a disguising symbolism or hiding behind some rationalizing explanation of them, such as this of the play.

They appear therefore as the buffetings of the future, from certain ones of which there is no escape on any of the paths that may be chosen. How then can these things be for the heroine from within herself? This inner self, where such wishes are stimulated and out of which they seek such indirect exit, is not like the rational self which we know in our intercourse with one another. Because of the asocial nature of its wishes, the direct self-gratifications which they seek to obtain, they are obliged to hide themselves or express their power in such obscure and devious ways. Their unconscious harborage is notwithstanding intensely emotional and the manner of thought which surrounds them is that of phantasy, different from the clear, logical, purposeful thinking of consciousness. Their logic and purpose lie only in the direct emotional impression of themselves into some manner

of fulfilment, and this in the face of reality must be largely only phantasy and pure wish. Do they escape, thus governed by phantasy, they distort reality to themselves and produce the disorder and distraction, the disappointment, suffering and pain, in which the various "episodes" end. They have a service to perform if they silently, unconsciously contribute their influence to the clearer rational way of life, but escaping its control, they work unrestrained havoc in individual and society.

Such the wishes paint the future before Gina. As the poet Hebbel has said of dreams, they "glide like shadows through the soul, preparing, warning, comforting," but the comfort here turns to fear and pain when she awakens, as do the dreams of the night when at the point of waking they pass over to the inspection of consciousness, and the wishes of which they are made must become unrecognized as such in order to pass this exacting censor. Gina's vision came too close to the wishes as realities for her recognition of them as in any sense her desires. They must be clothed with fear, shrinking, condemnation, and, with the same familiar mechanism of shifting responsibility, as due to environment, the work of those who surrounded her.

Perhaps it might be hardest to admit that the first "episode" contained a pictured wish fulfilment. Surely in the somber and despairing close of the five years of humdrum service for her family, in all the loss and bitterness which were her lot, there seems nothing that could claim the roseate title of wish. The wishes which hide in the unconscious are nevertheless frequently strange to ordinarily recognized ways of thought. They do indeed hide a certain strange pleasure upon which the ego feeds, a negative form of pleasure which extracts nourishment for the pleasure sense from suffering, self-pity and self-immolation which in the depths satisfy the ego sense. This therefore is only a strange disguise for the more positive seeking which desire primarily knows.

Beneath this pathway of Duty, behind even Gina's perplexity, which is the cause of her peering thus into her own unconscious depths, is a race old problem. It is the difficulty and inner reluctance with which the child separates from an innately indolent dependence upon parental love and care. Examination of the effort of both parent and child to make this necessary separation, whether it is observed throughout the history of man's racial development or through investigation into the difficulties of individual life, reveals that this bond is a stronger one than has carelessly been supposed. It is founded in an intense love and desire of the child toward those upon whom it has leaned for earliest absolute comfort, support, care and affection. The parent is the object of childish desire and of that more active aggressive seeking of a love object, which is early awakened, and directed first of all toward those upon whom the child thus leans. Toward these, in its narrowed environment, its feelings take on an intensity, which is not always sufficiently displaced in later life upon more external objects, be they persons or objects for endeavor.

Moreover, since the child is already a sexual being this love has a tendency to go out more posi-

itively toward a parent of the opposite sex. Therefore a certain fixation upon such a parent may manifest itself in later life, or at least it will color and determine later events and later object choice. This too forms a normal guide for the maturing child, only it also forms a source of danger as the normal use of this early tendency is exceeded and too great demands are made therefore upon maturity to conform to the child's early pattern of wishes.

The parent is often no more free than the child in this matter. Thus Gina's father with his almost whining dependence upon her domestic care and affection, as well as his grosser desire to sell his daughter's hand for his own comfort and release from care, blocked the way to his daughter's path of independent self-expression. He complicated the problem which was vexing not only her conscious sense of duty, but more deeply the unconscious struggle she was making to be free from her own inclination toward him. The unconscious impulse to prostitute herself, which fairly shrieks aloud in the second vision which she has of herself, is more quietly and so more distractingly at work even now. It too had precipitated the perplexity and the desire to gain help for her choice.

Prostitution is a trailing into present society of certain ancient elements in a woman's love or sex complex which once in a far more primitive society and on through advancing periods of its history had definite social service to perform. She as a weaker party before male aggressiveness could only demand certain rights for her protection and reward. In the earliest forms of society of which even unwritten record can be found, she was curiously protected in the demand for these rights and in the exercise of them by some male member of her own family, usually her elder brother. She maintained under his protection an exalted right in the tribe over her children, and sometimes their property and succession. Even in ancient civilizations as well as in the more barbarous conditions of many savage tribes, it was her duty and privilege to become the property of a stranger or group of strangers, either before marriage or even, perhaps with a religious sanction, during marriage. Thus was her promiscuity a part of her past history, an affective element which takes its place in the preserved past of emotional experience and uncultural desire, once cultural now no longer so. This is doubtless closely intertwined, since it was her exercised right, function and duty, not only with her mere desire, a past source of exercise and therefore of pleasure for her, but through it she found her source of power, when power avenues were largely closed to her otherwise. She even in earliest times is known to have contributed to the brother's prestige by bearing children by her husband or other lover to count as the brother's own. Her own power and prestige lay therefore for ages in the use of her body. Through it alone she was exalted above man, dominated him. This was not one man, but many men, and yet in most ancient periods at least, for the service of male members of her own family who were thus particularly in her power.

Such light from the remotest depths of the past into which we can peer, shines forth with almost

uncanny brilliancy in the light of Gina's possibilities revealed in her visions. They are the result of these anciently inherited impulses based on ancestral experiences in the past. She strives to break away from father and brother, but even when freedom seems to have been gained, she too utilizes her power over other men, to bring through her rewards, both father and brother into the dominance by which she makes them dependent upon her. Unconsciously she plunders other men while they destroy her, and hurls her plunder at the feet of the father and brother whom she would thus dominate and enslave.

Therefore even in the first vision, clothed in the garment of self-immolation, abandoned to tears of self-torture, she has sacrificed herself to keep them still in her power. Duty is the word with which she covers it all, most securely from herself. Duty is the word impressed upon her by the weak and faithless Louis, faithless throughout all the possibilities of her future. She has adopted his craven word only to find herself in the end its dupe and victim. Her father is dead, beyond her power of support and comfort, the brother Kenneth has grown pitifully weak and inefficient in his dependence upon her. Her sister has been flung into the arms of the unfaithful lover who once prated of duty to her.

She has realized upon herself and those whom she should rather have set free to wrestle with reality for themselves, an unconscious wish to be all to them, to exercise the peculiar power which only a woman has. Unable to escape to an external love, that which for the modern woman can truly lie only in mutual service and mutual freedom, she has remained in the father's house, close to the brother too, and has met only loss and disaster for them all. Still the unconscious is able to extract something for self, the revery of bitter grief and freely shed tears. She awakens however from such an insight into possibilities within herself, repulsed, but assured that here is not the reality of her true path. She will look again.

This is the vision in which her prostitution runs riot. The gleam of power through her voice had led her, but had soon been exchanged for the false brilliancy of love's basest conquest over men. It had been the influence of the man first who had stood in a fatherly relation to the unprotected girl, but who failed in his protective power, rather initiating her into the life which was the expression of the fundamental sexual father complex. She had escaped the unconscious incest bondage at home only to find it confronting her in the mocking disguise of a sexual experience with this older man, which was the beginning of the riotous course of prostitution and domination, up to the last silly exhibition of her power to defy her operative engagement and fling herself more completely to the infantile form of pleasure and power. It is the final culmination of the dominance, gathered in the brother, for whose sake and the father's this state of affairs largely existed, which breaks the destructive spell. When she has flung him to the lowest depth of destruction of the father representative who had been her ruin, and perhaps the brother's own final destruction, then the vision breaks. The girl can bear no more. As in the

dream such wish must be brought to the light of consciousness for denial, rejection, for some other, better way to power.

One more vision however must clear the unconscious atmosphere and give her final freedom of choice to use in a wiser way these powers hidden within her soul. This time she will yield more distinctively, more consciously to the father's wish. As it streams before her out of her own psychical possibilities, it must be her own wish also. Prostitution is decently clothed here in society's sanction, the father's material comfort and freedom from care, with beside the added element of the attention and consideration of a grave gentleman, apparently desirous of her self as well as to make her comfortable and well provided for.

The unconscious slavery, which is that inner fixation upon the father, in the infantile form of demanding the father's love, provision, whatever makes up the child relation to the father in the intense self seeking of the father, this breaks forth in blackest shadow in this episode. The dominance which she has unconsciously sought, providing again through herself for her father and family, turns upon herself. She is the worse than slave. She is scorned and spurned, flung aside without the slightest consideration. Her value as the man's social and sexual bauble is utterly at an end. Perhaps even the despicable manner of her downfall apparently put upon her by the man who despises her, but in fact arising in her own subjective vision, are again a picture of the possibilities which her own wish could project into this pathway of the future. So again it is with the fact of her own inner possibilities and therefore sense of guilt with which she wrestles. No wonder then that morphine becomes a refuge. No wonder also that even in the dream, the vision, she struggles even in the weakened drugged condition against complete downfall again and though poor, in need, friendless, lost to her social world, yet keeps herself here true to the pure ideals of her girlhood home. And this one of the three "episodes" ends through its sorrow in hope and promise of joy and life.

She is prepared for the waking. This is like the so-called "preparing function" of the dream of the night, which after long struggle, yielding to primitive, uncultural wishes, and slow conquest of them, seems at last to take up the path out into light and victory. One who has been submerged in the power of the baser unconscious wishes and the conflict with them, as in a long neurosis, comes after a more decisive and clearer wrestle with them through analysis of them to a new form of wish. The way out into a new adaptation to reality comes at last through an understanding of what the more primitive wishes are and where lies their ancient value and their still present power. A pathway is found to bring that power and value out into a higher cultural life, which is the sublimation of them. To this the dream itself finally points the way.

So has Gina won victory for herself and for those whom she would have made thus blindly dependent upon her, absorbed in her dominating power. Kindly but assuredly she refuses this last wish of her father, as she had refused the other two courses which had presented themselves to her. This time her father seems likewise to have at-

tained a new freedom. This comes about through no mystic subtle influence. It results from Gina's simple matter of fact grasp of reality for him and for the brother. Her sublimation is very real and very complete. A few clear suggestions to the father that he shall simply utilize the reality which is at his hand and take up his own problems, take them up with the cooperation of the active young son, to the advantage and for the opportunity of self-expression for both, breaks the spell of domination and dependence. Then she herself is at last free to turn to the one lover with whom she can meet on free and equal terms of mutual endeavor and enterprise. Eyes of Youth are at last cleared to see their way beyond the confines of inner fixation out into the privilege and possibility of a maturity freed from the bonds of infancy skulking under false names and deluding pretences.

There is no boundary to the past undulating behind us. The future remains dark and impenetrable before. Life's activity finds itself however upon the clear moment that looms up instantaneously between past and future. All that, like this play of the theater, reveals to us more of the actual content and power of that past, releases us from its bondage and gives us a freedom to receive its influence and fit it successfully and constructively into this quickly fleeting present moment. In this way and this alone the future becomes ours. We do not penetrate it. We have no definite visions as to where we shall walk and how. But its possibilities come within the range of our understanding, and we have a better nobler task than walking a clearly defined path. It is ours to grasp the influence of the past, apply it to reality, to opportunity, so that we make, create the future and mold it to progressively constructive ends.

64 WEST FIFTY-SIXTH STREET.

CANCER DEATH RATE IN NEW YORK CITY DURING 1917.

BY L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK.

SENIOR PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, ETC.

IN 1914 the New York Board of Health in its Monthly Bulletin for April presented a long article from the American Society for the Control of Cancer on "Cancer as a Public Health Problem." From this some data may be quoted.

Based on the statistics from the United States Registration area up to 1912, it showed very clearly and indisputably the steady and great increase in the mortality from cancer from the year 1900, when it was 63 per 100,000 to 77 per 100,000 in 1912, or 22.22 per cent. In New York State the increase had been from 66 in 1900 to 86.5 per 100,000 in 1913, or over 30 per cent. In New York City it had risen from 63.3 in 1898 to 81.7 per 100,000 in 1913, or over 29 per cent. Throughout the world the cancer death rate from 1900 to 1909 had advanced, on an average of all countries reporting, 23.3 per cent. Cancer was rightly spoken of as "a menace to society."

The question of the apparent or real increase in mortality was discussed, and it was remarked that "it seems unlikely that accuracy of diagnosis has advanced at such an even rate as to result in almost

exactly the same addition to the recorded cancer death rate each year."

Since 1914, when there was started the active propaganda for the more radical surgical treatment of cancer, the increase in the death rate has been much greater than before that time. Thus in the United States the mortality figure has steadily risen, so that in 1915 it was 81.1 per 100,000, or a total rise of 28.7 per cent, since 1900. In 1916 it was 81.8 per 100,000, or 29.84 per cent increase since 1900.

It is a little interesting to note that during the five years immediately preceding 1915, at which date surgery became more active, the mortality rose only from 76.2 to 79.4, a total of 3.2 deaths per 100,000 population, or much less than one per year; while in 1915, after the vigorous educational and surgical propaganda, the death rate rose from 79.4 in 1914 to 81.1 per 100,000, or 1.7 more deaths per 100,000 population in a single year; this is an increase of 2.13 per cent, more than double that in the preceding years. Could this be ascribed to more accurate diagnosis?

A confirmation of the reality of the increase in deaths from cancer happens to come in the Bulletin of the North Dakota State Board of Health for October, 1917. In it we find a quarterly mortality summary of all the deaths during July, August and September, 1917, with a column comparing these with the data of 1916. We find that while the general death rate, partly or wholly due to increase of population, had risen 22 per cent, the increase in the cancer death rate had increased 30 per cent—from more accurate diagnosis?

Turning now to the mortality from cancer, in New York City, in 1917, as shown in the Weekly Bulletin of the New York Board of Health, we find that there were 4,859 deaths recorded from cancer, malignant tumor, 2143 males and 2716 females. This total number divided by 365 gives 13.33 persons dying daily from this cause. During 1916 there were 4635 deaths from cancer, or 12.68 persons per day.

During 1917 there was a total of 78,467 deaths from all causes in Greater New York against 77,948 in 1916, an increase of 519, or less than one per cent; whereas the increase in cancer deaths was 224 or almost five per cent. Surely such figures, which cannot lie, and which show an increase of cancer mortality nearly five times that from general causes, cannot be explained away by greater accuracy of diagnosis or more perfect recording of death certificates.

In all this study of mortality statistics it is well to remember that these figures do not necessarily represent truly the real increase of cancer as a disease, which is probably even much greater than the figures show. For undoubtedly many cancer patients die of intercurrent diseases, under which the death is recorded, and in many instances the diagnosis of cancer is withheld from the death certificate for personal or family reasons.

The alarming increase in the death rate from cancer under surgical care may well be compared with the notable and steady decrease in the deaths from tuberculosis under rational and careful medical supervision and treatment. In 1900 the death rate from tuberculosis, in the United States Regis-

tration area, was 201.9 persons in each 100,000 population, and by 1916 it had fallen to 141.6 or a decrease of 60.3 persons in 100,000, or almost 30 per cent; whereas during the same period the death rate of cancer had risen 29.84 per cent! In 1900 the two diseases were 138.9 points apart in mortality, and in 1916 only 59.8 apart; at this rate of increase and decrease cancer will soon claim more victims in each 100,000 population than tuberculosis.

In the light of what has preceded is it not possible that there is something wrong in our conception of cancer and its treatment, as I have repeatedly endeavored to show? If any other disease presented such a steady and alarming rise in its death rate would we not stop and consider if our treatment were the best possible? If, with the introduction of antitoxin, the mortality from diphtheria had steadily risen until it was 90 per cent of all cases, which is the acknowledged ultimate death rate of cancer, would we persist in employing it? And yet the profession and laity go blindly on with the idea that surgery offers the best and only hope of reaching cancer, by removing a local lesion which is only the *product* of a previous constitutional departure from health. As well might one excise a syphilitic gumma, or a tuberculous lesion, or amputate a gouty toe, without other treatment, and hope that there would be no further trouble; for all experience shows that cancer is exceedingly prone to manifest itself anew, either in the same location or elsewhere.

It is a curious comment on human credulity that with this steady rise in its mortality so many should have accepted the dictum that cancer was only a surgical disease, and reached only by surgical measures, when all along the past one hundred years single voices of surgeons and medical men have now and again spoken so strongly in favor of its constitutional origin, as I have shown in my first volume. The lure of surgery is very strong, and surgeons have made great claims, while medical men have not yet reported any single specific for the disease—for the single reason that no specific will ever be found.

It is not the purpose of the present writing to enter upon the proof of the constitutional nature of cancer and its successful treatment by other than surgical measures, which have been abundantly considered in the books referred to. It can, however, be truthfully claimed that under proper and prolonged medical treatment more can be effected than with the knife. Not only is the death rate smaller, but the ultimate suffering is less. Moreover, with the fear of an operation removed, together with the known uncertainty as to the ultimate result, patients would be more inclined to seek aid in the earlier stages of the disease, when the prospects of overcoming it are better.

531 MADISON AVENUE.

*Cancer, Its Cause and Treatment. Vols. I and II, P. B. Hoeber, New York, 1915-17.

Collargol in the Sepsis of Children.—Bogen injected collargol into the veins in desperate cases of sepsis in childhood, both cryptogenetic and postanginal. The typical reaction—sharp rise of temperature after 2 to 4 hours, chill and profuse sweats—is indicative of recovery.—*Jahrbuch für Kinderheilkunde*.

MASKED PELLAGRA.

BY J. F. VARBROUGH, M.D.,

COLUMBIA, ALA.

OSLER states in his "Practice" that a type of pellagra without the dermatitis had been described, but his dismissing the matter with this short notice would lead one to infer that he was in doubt as to the existence of such a type. I am sure the profession at large are also doubtful of its existence.

My hospital records for the past several years, to my mind, offer sufficient proof that it does exist. I am sure more than a third of the cases are of this type. It is diagnosed "hypochondria," "hysteria," "neurasthenia," "nervous indigestion" — blanket terms that mean nothing and serve only to cover our ignorance.

When we come in contact with a case of this type, we usually make a diagnosis something like the above, and never stop to dig out the real cause of these nervous manifestations.

When we hear the sound of the rattles we know the snake is there, but it blends so cunningly with the surrounding objects it is almost impossible at times to bring it clearly into view. So when we come in contact with this type of the disease, and hear the rattles (nervous phenomena) we have been taught to look first to the ovaries, then to the tubes and uterus, name it something, prescribe a douche and a "nerve sedative," and go on our way without having had even a glimpse of the real snake. These patients drift from physician to physician, from hospital to hospital, are operated on for various things until death kindly closes the drama.

I do not mean to say that all nervous manifestations are the result of this type of pellagra, but, when they cannot be traced to a definite cause, it would be well to give pellagra serious consideration.

My hospital records, as well as those of many of the asylums, I think, prove conclusively that many physicians are having difficulty in recognizing this type of the disease; therefore the purpose of this paper is to provoke thought and discussion of this, the most important scientific problem now confronting Southern physicians.

The difficulty in diagnosis may be emphasized by two or three examples.

Mrs. S. had been treated seven years by various physicians for ovarian, uterine, and other disorders. At Hot Springs she was treated several weeks for "neurasthenia"; her condition became so serious she was carried to the asylum at Tuscaloosa, Ala., where Dr. Searcy promptly made a diagnosis of pellagra; she was brought here and made a good recovery.

Mrs. W. during the past fifteen years had run the gamut of all the "nerve sedatives"; there had been many diagnoses, and a number of operations advised; at Mobile, Ala., Dr. Bonduant made a prompt diagnosis of pellagra. In the sanatorium here she made a slow but sure recovery.

Mrs. M. had been treated several years by many of the best physicians of Georgia; "nervous indigestion" seems to have been the general diagnosis; at Milledgeville the case was diagnosed pellagra; her recovery here was all that could be desired.

Dr. A. S. Frasier, of Dothan, Ala., has been able to diagnose, and kindly refer, a number of these cases to me. A great number of examples of this character could be given; these are enough, however, to emphasize the point made.

None of these cases exhibited any evidence of the dermatitis. When we once have a clear picture of this condition our future diagnoses are comparatively easy. To get this picture without clinical experience is a difficult matter, because we have been taught that these nervous phenomena are of entirely different origin.

Symptoms.—*Skin:* There is no dermatitis in this class of patients, except that it does appear in a small percentage of the cases a short time before death. The skin has a peculiar muddy pallor hard to describe; it reminds one more of toxic pallor than of anemia; it is not a real anemia, the blood count is usually normal, but there are a few cases in which a real anemia exists. The burning sensations of the lower limbs and feet are very often but not always present.

Oral: The mouth and throat present a variety of symptoms; some tongues are red, irritable, and deeply fissured, others have a sleek, burned appearance, still others present a gray putty color without tone or shape, just a dirty, flabby mass; in some cases the tongue shows no evidence of the disease except a burned sleek appearance of the margins.

The throat presents a symptom of great diagnostic value. As far down as it can be seen to a well defined line just above the pillars of the fauces it presents a red, irritated appearance. In many cases the line of demarcation is as well defined as is that of erysipelas; as the disease advances the redness gradually extends to the entire buccal cavity.

Gastrointestinal: In some cases the digestive symptoms are of minor importance; in most instances, however, they assume major proportions.

Tenderness over the entire abdominal area is not an infrequent symptom; it is usually out of seeming proportion to the illness of the patient; by it the colon can by gentle palpation be definitely traced.

Constipation is almost always present, although I have seen mild attacks of diarrhea in a few instances.

Dreaming: Dreaming is a most annoying symptom in many instances; on waking the patients relate some of the most horrible experiences imaginable through which they have passed; some of them endeavor to hide this symptom and deny for a long time that they ever have any such dreams.

Weakness: This is not an uncommon symptom in this type of the disease; it is observed most frequently in those whose mental faculties are the least involved. Except for the toxic pallor they seem to be in fairly good health, but on the least exertion they become out of breath, the limbs tremble and seem unable to support the trunk. This is not dyspnea from cardiac insufficiency, but seems to be due to a lack of nervous tone.

Mental: I fully realize that I am here entering on dangerous ground; however, I believe our knowledge of this type of the disease has progressed to the point where by a painstaking, thorough investigation we are able to differentiate between these nervous manifestations and those of other diseases that present a like symptom complex.

Fear: Fear is one of the cardinal symptoms of this peculiar psychological condition; the patients are in a general state of fear, fearing themselves, as

well as everyone and everything with which they come in contact, and are never able to give a definite reason for their apprehensions. Their facial expression is one of impending danger, with a puckered, furrowed brow.

The genuine psychoneurasthenic may be easily eliminated from this class because of their ever ready voluminous reasons for the impending catastrophe. In genuine depressive mania the patients always ascribe their misfortunes to some personal transgression.

Irritability: It is generally conceded that Shakespeare got his inspiration for "The Taming of the Shrew" from the common scold; the lay mind not being versed in the finer points of psychoanalysis may have easily confounded the scold with this type of pellagrin; there is, however, a wide gulf fixed between the two; the pellagrin is irritated with himself because he is irritable; he recognizes that he is disagreeable to his family and friends, but is unable to remedy the condition. The scold is never conscious of being in the wrong, the other party is always the offender, and he seems to take delight in making himself as obnoxious and disagreeable as possible.

Melancholia: Melancholia is a very grave factor in patients of this type; their deeds of murder and suicide fill the daily press. For obvious reasons it is extremely important that these cases should be recognized and treated at the very earliest possible moment.

Confusional: The stenographer is unable to write an intelligent letter. The mail carrier is unable to assort and deliver the mail. The plowman runs a furrow across the field and cannot properly follow it back to the starting point. The farmer starts to drive his stock to the pasture and then wanders off in the fields, leaving the stock to destroy his crops.

This condition may progress to the point where it closely resembles acute manic-depressive psychosis; the distinguishing feature is that it reaches a definite conclusion much more rapidly than does mania.

Delusions and hallucinations are rare in these cases; however, they do occur. One of my patients knew that his family had been ruined by a wealthy man in the community, and that his life was in danger; he could hear them planning to assassinate him; he called the Governor over an imaginary telephone and asked for a company of soldiers to protect him; the Governor granted his request, and as soon as he believed the soldiers had arrived he became calm and satisfied. This man recovered.

I have seen delusions and hallucinations in the insane and alcoholics, but the picture is not just the combination as we see it in the pellagrin.

Conclusion.—The presence of burning sensations of the lower limbs and feet; general digestive derangement; tenderness over the abdominal area; weakness without seeming cause; redness of the throat extending to a well defined line just above the pillars of the tonsils; a red, sleek, fissured, or putty-colored tongue, and the peculiar nervous symptoms described above, I believe warrants us in making a positive diagnosis of pellagra, although there is no sign of dermatitis.

SOME FRAGMENTARY NOTES ON PARKINSON'S DISEASE AND ITS TREATMENT WITH PARATHYROID GLAND.*

BY WILLIAM N. BERKELEY, A.B., Ph.B., M.D.,

NEW YORK.

ATTENDING PHYSICIAN AT THE GOOD SAMARITAN DISPENSARY.

IT is just 100 years since James Parkinson's classic account of Shaking Palsy was first published in London. In his Preface the author observes, with truth and feeling:

"The disease respecting which the present inquiry is made is of a nature highly afflictive. . . . The writer will repine at no censure which the precipitate publication of mere conjectural suggestions may incur, but shall think himself fully rewarded by having attracted the attention of those who may point out the most appropriate means of relieving a tedious and most distressing malady."

These words shall be an *apologia* for the present fragmentary comments.

I shall not dwell upon the literary history of shaking palsy. The story would take a long time and fill many books. The symptomatology of Parkinson's original account is quite full. Later writers have added *Paralysis Agitans sine Agitatione*, and a rarer form *with* shaking but *without* any marked rigidity.

All races of men appear susceptible. Charles W. Burr¹ has reported a case in a negro of advanced years, and expresses the opinion that the supposed immunity of the negro race to this disease is an error.

As regards age incidence it was believed for a long time that paralysis agitans is strictly confined to the second half of life, not appearing before the third decade. H. Willige² has, however, carefully reviewed the literature, and thinks that some of the reported cases occurring as early as the twentieth year must be acknowledged as genuine. Several of these he considers "familial," and evidently a "special type." J. R. Hunt³ has reported a case of the *paralysis agitans syndrome* beginning in the fifteenth year of life. The autopsy showed what Dr. Hunt designates as "destructive lesions of certain groups of cells in the globus pallidus." He, too, believes the young patients constitute a special type, and thinks that further study will differentiate also many of the older cases. His views await further investigation. The literature contains between forty and fifty other pathological hypotheses based upon one or two autopsies, and without subsequent confirmation.

The confusion and contradictoriness of autopsy reports long ago led C. L. Dana and others to advance the view that a chronic toxemia lies at the base of the disease; and it was suggested by Lundborg of Stockholm⁴ in 1904 and by myself⁵ independently in 1905 that a *chronic dyscrasia or insufficiency of the parathyroid glands* is quite possibly the cause of the disease.

My own reasons for this view have been frequently stated before, and need be only summarized now: (1) The symptoms appearing in rabbits and other convenient experimental animals upon removal of the parathyroid glands are sug-

gestive; shivering and twitching of the voluntary muscles, rigidity, convulsions, salivation, and often a quite typical "propulsion" may be observed. (2) The disease has been reported several times in conjunction with myxedema, and with exophthalmic goiter, where the contiguity of the diseased thyroid might well be supposed to work mischief to the parathyroids. (3) The parathyroid glands have been reported in a diseased condition in a fair percentage of the autopsies upon cases of paralysis agitans; and finally, (4) The use of a properly prepared parathyroid extract by the mouth, or better by hypodermic administration, has been productive of remarkable benefit in a majority of the cases treated. This therapeutic test has been applied to hundreds of cases during a period of more than ten years past; and the treatment has shown a steady and gratifying increase in popularity.

Admittedly these considerations are by no means a *demonstration* of the etiological relation of shaking palsy to parathyroid insufficiency; but the hypothesis certainly comes within the bounds of reasonable scientific speculation.

By the profession both here and in Europe, during the last 10 years the parathyroid theory has been received with considerable favor. In *International Clinics* for 1912, I reviewed⁶ the literature—mostly favorable—up to that date. Since then J. Greenwald⁷ has advanced some interesting but I do not think conclusive chemical considerations *against* the parathyroid theory. Troemner⁸ thinks the parathyroid hypothesis "possible;" and Schioetz⁹ defends it with considerable enthusiasm.

I take up finally the clinical administration of parathyroid, as I am accustomed to give it.

First of all, it is absolutely necessary that an efficient preparation, made from perfectly fresh and carefully identified glands, should be used. The chemical details of my own extraction process, which I have worked out after many years of experiment, have been published in several places, and need not be again detailed here. My formula is now for sale by several New York pharmaceutical wholesalers. It comes in small capsules (one-fiftieth grain of parathyroid extract in milk sugar), and as hypodermic solution; the latter is marketed in small rubber-stoppered bottles of five mils. The hypodermic is the ideal preparation, but is more expensive, and many patients do very well on the capsules.

The dose by the mouth is one capsule two to six times a day, preferably after eating. The hypodermic solution is given in doses of one or two mils once or twice a day. One mil contains one-fiftieth grain of the extract. This arrangement evidently mixes the metric and English systems, but is justified by its convenience, and is easily remembered. The solvent is physiological saline solution. A trace of chloroform is added as a preservative. Aseptically injected, the hypodermic solution should be absolutely without reaction.

The *benefits of treatment* usually appear slowly. They consist in diminished rigidity, shaking relieved or arrested, restlessness and insomnia relieved, and salivation abolished. In some of the cases now and then quite a miracle is performed, as for example in a report recently published by Dr. George Martyn.¹⁰ The writer states that the patient,

*Revised from an address before the Clinical Club of Yonkers, New York, Dec. 4th, 1917.

whose condition had been desperate, was so remarkably benefited that he was enabled to bathe and dress himself, read and write comfortably once more, sleep well, and amuse himself by pruning his own orchard trees again—a pleasure in which he had not been able to indulge himself for a long while. The only setback occurred when for a period of a week or so he was unable to get a fresh supply of the medicine. I myself last year reported two cases which have lately attracted my special notice. One of them, the father of a medical associate in the Bronx, has been literally kept alive by my parathyroid formula these ten years back.

Contraindications are very few. Personally in many years and with more than a hundred patients, I have seen only one, an elderly man, living in Hamilton, Ontario, who could not take ox-parathyroid at all. He seemed to have an anaphylactic sensitivity to the foreign proteins. This may also have been the trouble with a patient last year in the care of Dr. G. Clarence Parcher, of Saugus, Mass., whose account (private letter) has interested and puzzled me considerably.

Some patients get "nervous," and shake worse when the dose is pushed too fast. To these the remedy should be given in divided and infrequent doses till they become accustomed to it. I have one patient who is sure the parathyroid constipates him; but he overcomes this very easily with a simple laxative.

Improvement is often noticed in two weeks, very generally in two or three months; and it should continue for a few months more. After this the remedy should be indefinitely continued, but in smaller doses—just enough to maintain the benefits already secured.

Cardiac disease, arteriosclerosis, and albuminuria are no contraindications. These conditions may even improve under the parathyroid treatment. None of the textbook remedies for the intercurrent diseases of old age is incompatible with parathyroid extract. Hyosine and parathyroid sometimes go very well together, working better than either alone.

Easy travel often benefits these patients, and they are appreciably sustained by cheerful company, a hopeful environment, or perhaps an appeal to their religious faith. Institutional cases do badly, for reasons too apparent to require amplification. The sufferer should by all means be kept out of a hospital atmosphere.

Under these circumstances, and with an intelligent individual application of the principles of treatment outlined above, these patients often do very well for many years, reaching and passing the scriptural threescore and ten with but little more inconvenience than usually befalls normal old age.

THE UNSTABLE QUALITIES OF DIGITALIS PREPARATIONS;

EXPERIMENTAL TESTS AND MEANS OF PREVENTION
RELATED TO THERAPEUTIC EFFICIENCY IN
CARDIOVASCULAR DISEASE.

BY ERNEST ZUEBLIN, M.D., F.A.C.P.,

CINCINNATI, OHIO.

ASSOCIATE PROFESSOR OF MEDICINE, UNIVERSITY OF CINCINNATI;
RESIDENT MEDICAL DIRECTOR, CINCINNATI
TUBERCULOSIS HOSPITAL.

IN the treatment of cardiovascular disease the physician in charge of obstinate and chronic cases often faces a hard problem how to secure relief for the patient. An investigation into the cause of our failure may reveal a defective diagnosis, an erroneous treatment, lack of co-operation from the patient, etc. Since the regulations of the Pharmacopœia must be closely followed the practising colleague feels pretty sure that the needy patient is well provided with active drugs.

Individual curiosity and search for more knowledge and truth at times makes us feel as if we have unraveled all or most of the laws governing nature. Usually in the search for an answer to a definite question, we may solve the same, but always there remains something new to be investigated and at the top of that ascending grade of knowledge we notice the bright inscription "per aspera ad astra," by effort to reach the stars.

The task of instructing the medical student has become wider and more extensive since there has been added to inorganic and organic chemistry the problems of colloid and physical chemistry as new and promising fields of investigation. Nobody today will question the importance of these subjects for pharmacology and therapeutics and these branches of science are not as yet sufficient for giving an answer to the many questions we would like to have answered satisfactorily.

Since the discovery of radium and the many interesting qualities of these substances revealed by many investigators—Madame Curie, Rutherford, Soddy, Geiger, and others, the cherished conception of the non-divisibility of the atoms as a basic foundation to our conception of matter has been shaken since we must recall the new interpretation of the atom as a complex of ions and electrons held in a state of equilibrium. Any disturbance of the latter is followed by the display of energy—heat, ionization, chemical radiation—a law accepted by notable physicists, among which the work of Thompson stands so prominent.

Stimulated by the interpretations of radioactive substances in the course of original research work in the past four years I examined numerous chemicals and pharmaceutical products under the fontactoscope—an instrument constructed for the purpose of

*Paper read before the Cincinnati Research Society on December 6, 1917.

determining the amount of radioactive rays emitted by the radioactive bodies.^{1, 2, 3} What at first appeared to me as an interesting fact is that all substances so far examined reveal a discharge of the leaflets of the gold electroscope. More than 6000 tests have been made, each extending over an observation period from a few minutes to several hours, all with a similar result, namely, a gradual discharge of the instrument in excess of the surrounding air which had been tested before the substance was investigated. Such a discharge can be noticed with either a positive or a negative charge of the instrument. This phenomenon can be measured in volts or in electrostatic units or in Mache units as used in the radioactive bodies—radium-thorium series—or it may be measured as ionization and applying to a larger group of chemical combinations. The final decision as to the quality and nature of this electric discharge whether due to ultraviolet radiation or to chemical rays, as alpha, beta, gamma rays, is a problem for the physical laboratory to answer. Besides the scientific interest of such phenomena the question arose whether clinically these qualities, present in medicinal substances, might be of value. I cannot enter into that problem to-day, but would refer to my former publications on that subject, dealing especially with antirheumatics.²

To-day I would call attention only to an investigation of the radiosopic qualities of the cardiovascular stimulants, especially digitalis preparations. I shall not attempt to quote the tables and the individual readings expressed in scale divisions of the instrument or quoted in volts or Mache units for a definite weight, the question is simply this: Can we notice any change in the charted discharge? A glance over the different curves will reveal the result of my investigations, but a few explanatory remarks may precede their discussion. We notice the horizontal line, or zero line, above which the scale readings of the positively charged instrument are recorded, while below the zero line we see the charting obtained under negative charge of the fontactoscope. As intimated before, for every determination the ionization—normal loss—of the air has to be carried out, represented by the dotted line. The heavy line refers to the substance proper examined under identical conditions. For the reading of the curves a clear understanding of the exchange of ions in the recipient is necessary. I must mention one of the principal rules of physics in which the negative electric current tends to be neutralized by the same amount of positive electric energy. The leaflet electroscope being charged with positive electricity, the leaflets are kept as far distant from each other as the insulation will permit. In the recipient containing the air or the substance in which ionization is in progress, the negative ions reach the condenser and in neutralizing they take from the positive charge just the proper quantity, consequently the tension of the leaflets is diminished, they approach each other as observed on the scale at definite time intervals, equivalent to a definite voltage. As in air we have always positive and negative ions besides neutralized ones, it must be remembered that one quality may be in excess of the opposite ones, consequently the fall of the leaflets may be retarded or even be checked, or the charge may

be increased, as the case may be. If we remember that the beta rays are of negative charge, they will become neutralized when the fontactoscope is charged positively, and vice versa the positively charged alpha rays will become neutralized by a negatively charged instrument. Such a deduction applied to our curves, and in speaking of the line above the zero line as the beta line, and of the line below the zero level as corresponding to the alpha radiation may not be absolutely correct, since for the determination of alpha, beta, and gamma rays other physical tests, especially those of filtration through metallic screens, determination of the number of corpuscles, or the measurement of their wave length may be required,⁴ besides their effect upon the sensitive photographic plate. So, choosing a more simple term, we will simply speak of the positive or negative charge of the fontactoscope.

As to the curves, Nos. 1, 2, 3 refer to 0.002 grams of powdered digitalis leaves examined at various periods, always the same sample being used; test No. 2, 323 days; test No. 3, 136 days later, or 459 days after the first test, under the precaution that the digitalis powder was kept in a sealed bottle, protected from light and all moisture for all that length of time. Roughly speaking, in No. 1 we

CHART 1. CHART 2. CHART 3.

have above and below the zero line a considerable discharge marked in scale divisions and that in excess of the dotted line representing the normal loss or ionization of the surrounding air.

In test No. 2, carried out under identical conditions and precautions 323 days later, we miss in the charted line the steep ascent, and the normal loss is only slightly smaller from the energy given off by the digitalis leaves. With a negatively charged instrument we notice a steeper curve in which the normal loss exceeds the readings of the substance proper. This difference is again emphasized in chart No. 3 where we have in the positively charged instrument a slight discharge by the substance, much inferior to the normal ionization of the air. For the negatively charged instrument the normal loss is smaller and not so steep, leaving an excess of radiation considerably inferior to the first observation. As stated in former papers of mine, a comparison of the curves obtained with positive and negative charges of the fontactoscope indicates that the difference in the elevation of the curves may be due to an irregular discharge of ions, which being cast off, the positive ones as well as the negative

ones interfere with each other, so necessarily influencing the character of the curve of ionization.

Without entering too much into speculative deductions from the curves presented, we must admit a gradual change of the drug in the physical qualities

mal loss and substance curves pursued a more or less parallel direction. So for a closer study of the phenomenon it was desirable to divide the readings into periods of 15 minutes, making successive readings over one-half to one hour. Admitted the possi-

CHART 12. CHART 13. CHART 14. CHART 15.

bility of the greatest fall and discharge of the leaflets to take place in the first few minutes, on further readings the difference between normal loss and substance curve would either cease or become lessened. By carefully removing the bottom of the recipient containing the substance, replacing the ionized air by fresh air, this exchange being carried out without disturbing the electroscope itself, meant a delicate performance requiring some experience. The following charts, Nos. 8, 9, 10, 11, refer to readings made with triturates containing tincture of digitalis, 10-minim powdered tablets, the amount tested being 0.008 gram. A brief discussion of the curves so obtained will be justified, followed by a short review of the serial determinations. It will be noted that in No. 8 and No. 9 the fall of the leaflets, with positive charge of the instrument for the test substance is greater than the fall caused by the ionized air. The latter has a slight tendency toward increase, while the former reaches the same height in both determinations. Once the air had been changed we notice in the normal loss a moderate decline, while the substance curve appears at least not diminished. As a necessary consequence we find an increase in the net excess ionization over the normal loss. Contrary to our expectations of a lowered ionization discharge we see an increase of the same displayed which change cannot be interpreted as a discharge which lasts only a very short time.

The same substance, on being tested two days later, with bad weather conditions prevailing, as a rule yielded less good net results than with a bright and cloudless sky without any precipitation, and the results of such test are given in charts Nos. 12, 13, 14, and 15. Throughout the experiment we notice the leading elevation of the substance curve above the normal loss line. The latter in the course of the observation, also after the renewal of the air in the recipient, becomes slightly lessened. The substance curve shows another interesting peculiarity that in the first 15 minutes period the highest stand is recorded, which level is lessened at the beginning of the exchange of air, with a tendency to rise at the end of the second half hour. The net excess ionization over the normal loss in the stored preparation suggests the maximum difference just at the end of the first 15 minutes. Becoming less at the subsequent readings, this fact would not speak against an accumulation of energy which at the first opportunity would be thrown off. Although qualitatively, in two days interval, the discharge curve may differ, quantitatively, taking in account the final result, there is no difference to be ascertained in my observations.

As a result of my previous study showing a deterioration of drugs, especially of the digitalis preparations, with regard to their physical or electrical qualities, the problem is suggested, is there any means of preventing such a change? Just as in former studies,^{2-3, 6-8} in this field of investigation, theoretical reasons and deductions justified an exposure of digitalis products to electric high-frequency waves. The most effectual method of procedure for getting the optimum results is still in its experimental stage, but a chart of triturates of tincture of digitalis, containing 10 minims, by treating the identical material represented in the previous charts, Nos. 8-15, may be included in the present discussion. A glance at charts Nos. 16, 17, 18, 19, drawn on the same scale as the other ones, will show the higher curves which may be interesting. The method of renewing the air has been chosen, for the purpose of having a more delicate means of information at hand. In chart No. 16 we see a surprising leap upward in the normal loss curve as well as in the substance curve, resulting in an excess ionization for the treated substance. More instructive is chart No. 17, in which, as a consequence of the small normal loss and with a steep ascent of the substance curve, we realize a marked display of excess ionization from the treated substance. A renewal of the air in the recipient does not materially alter the leading ascent of the substance curve in excess over the steeper normal loss line. The fourth period reveals a decline in the normal loss curve, while the substance curve reaches a high level only little different from the one obtained previously. So as a general rule, even with a greater weight of the substance we find a decided increase of the excess ionization curve over the normal loss line, a result which was encouraging at least for further investigation of the subject.

I am aware that a difference in physical radiation or ionization can by no means be interpreted as an advantage which might benefit suffering patients, but we clinicians and research men we cannot get away from certain "dreams" which must stand the test of time by further experimental facts.

Since further experiments with high-frequency waves on patients with cardiovascular disease⁹ have justified the use of such means, why should it not be possible to impart the same electric energy to cardiovascular stimulants and by doing so add another trump card in the patient's game for his life? Further research work will, and must, reveal the probabilities of such a therapeutic attempt.

From the pharmacological standpoint, however,

CHART 16. CHART 17. CHART 18. CHART 19.

in concluding this communication, I am reminded of the old classic saying *tempora mutantur et nos mutamur in illis*. I would infer that matter never perishes but is subject to constant change which process should be investigated by the chemist, the

physicist, and last but not least by the pharmacologist in the selection of the proper drugs reputed for their gift of restoring health and so shortening human sufferings.

Medicolegal Notes.

Unauthorized Practitioners—Recovery of Compensation.—In an action for services rendered as a mechanotherapist the evidence was held to justify the amount of the judgment entered for the plaintiff by the trial court were it not that the plaintiff admitted that he had failed to comply with the laws of Missouri. He had no legal certificate to treat the sick such as is required by chapter 78 R. S. 1909, and was guilty of the criminal law, which made his act a misdemeanor, punishable by fine and imprisonment. The plaintiff, however, contended (conceding for the argument of the case that he had violated the criminal law of the State) that, notwithstanding this, he was entitled to recover under the existing law of Missouri because the statute of 1909 does not contain the provision contained in the former statute of 1879 that a person violating the law shall not be permitted to recover compensation for services rendered as a physician or surgeon. Differing from the prior decision of the St. Louis Court of Appeals, *Smythe v. Hanson*, 61 Mo. App. 285, where it was held that the omission of the provision as to a recovery for services indicated that the Legislature intended to abolish the penalty of not permitting a recovery, the Springfield Court of Appeals holds that as the later statute makes it a misdemeanor for the plaintiff to perform the services for which he was attempting to recover compensation, he was seeking to be paid for the commission of a crime; and contracts which are made for or about any matter which is prohibited and which is unlawful are void, and cannot be made the foundation of a cause of action. The law will not lend its sanction or aid to a claim based upon its violation. This rule is not for the benefit of the parties, but for the public good; and the medical act was passed for the protection of the public.

Practically every case the court found, except *Smythe v. Hanson*, holds that where a statute has been enacted fixing certain requirements in order to practice medicine and a penalty attached for treating the sick without having complied with the statute, there can be no recovery for services, and this even though the statute has no provision expressly prohibiting a recovery for services. The court considered the case of *McConnor v. Haskins*, 180 S. W. 21, decided by the same court, holding that, although a statute requires one peddling medicines to secure a license, the fact that he does not do so does not preclude his collecting for the goods sold, but merely makes him liable to the fine provided for the violation of the statute, and other like cases, were not analogous. In these cases the licenses in dispute were made necessary as revenue measures and were not required for the protection of the public. Another reason why such cases were not analogous was that the possession of a license or the failure to have one neither adds to nor takes away from the article or goods bartered or sold, the essence of the contract; whereas, the very consideration and essence of a contract made between doctor and patient is the skill, knowledge, and ability of the doctor; that is the very thing the patient contracts to pay for, and to insure the weak, sick and

infirm in getting a high order of skill, knowledge and ability when they contract therefor the law has wisely made certain requirements of those who can give and impart their skill, knowledge and ability in the treatment. It is for the public good that the services of professional men be of the highest character both from the standpoint of efficiency and integrity, and statutes passed to accomplish this result should be broadened rather than narrowed in their construction and application. Especially is this true when dealing with a profession charged with the treatment of the body. For these reasons it was held the plaintiff could not recover for the services rendered, but as this decision is in conflict with that in *Smythe v. Hanson* the cause was certified to the Supreme Court for final determination.—*O'Bannon v. Widick* (Mo.) 198 S. W. 432.

Medical Act Held Unconstitutional.—The Georgia Supreme Court holds that the act of 1916, amending the act of 1909, establishing a board of osteopathic examiners, by extending the provisions of the original act to all other nondrug-giving practitioners except Christian Scientists and masseurs, is unconstitutional because it seeks to impart into the act to be amended matter not germane to it and not indicated by its caption, and therefore offends against the constitutional provision that "no law or ordinance shall pass which refers to more than one subject matter or contains matter different from what is expressed in the title thereof."—*Ausbrooks v. State* (Ga.) 94 S. E. 304.

Occupational Diseases.—Under the Nebraska Workmen's Compensation Act compensation can only be made for personal injuries or for the death of an employee "by accident arising out of and in the course of employment," and unless a disease is traceable to an "accident" as defined in section 3893 the law does not award compensation. The Nebraska Supreme Court holds that a disease arising from the ordinary incidents of an occupation and which may reasonably be said to be the result of an occupation is expressly excepted by that section of the act, and no recovery can be had for disability occasioned thereby. There is a difference in the statutes of different states, and cases which in some states would be held to be within the law are in other states necessarily excluded. It is pointed out in the Bulletin of the United States Labor Statistics Bureau No. 203, issued in January, 1917, that the modifying term "accidentally" does not appear in the laws of California (as amended in 1915), Connecticut, Massachusetts, Ohio, West Virginia and the Federal statutes of 1908 and 1917, so that cases from those jurisdictions afford no light as to whether cases of this nature are within the Nebraska statute. In practically every case in which the workman was held entitled to recover which is at all similar the facts disclosed a sudden event happening at a particular time to which the injury was directly traceable. Within this class of cases are sunstroke, heatstroke, hernia, and injuries from freezing. In a number of cases recovery has been allowed for death from a subsequent disease such as pneumonia, and in such cases there has always been some accident, such as a miner being compelled by accident to the machinery to stand in cold water for a long time, or a pilot jumping into a boat which partly upset and caused him to become wet and chilled, resulting in sciatica, or some other accidental occurrence. The accident may not always have affected the individual directly, but it set a train of causative events in motion, to which the disease was directly attributable. Where a bill collector hurrying to finish his work became overheated, chilled by exposure, which developed into pleurisy, it was held an accident.—*Blair v. Omaha Ice & Cold Storage Co.* (Neb.), 165 N. W. 893.

Death from Accident or Disease—Express Provision of Policy.—The Utah Supreme Court holds that under a health and sickness policy providing that any loss resulting from septicemia should be regarded as resulting from sickness, and should require a payment of only the sick benefit, the beneficiary could recover, for the death of the insured from septicemia following upon a sprained ankle, only the sick benefit for the period between the time of the injury and the date of the insured's death.—*Anderson v. Great Eastern Casualty Co.*, 168 Pac. 966.

Military Medicine.

THE DYSPEPSIA OF THE EDENTATE SOLDIER.

AN attempt to isolate special forms of indigestion in the toothless has not, so far as we know, been seriously attempted by the gastroenterologist. Bolt-ing of food is common enough even when good dentures are present, and attempts have been made to show that the food bolter may constitute a separate physiological type of man to be distinguished from the food chewer. The former is analogous to the carnivorous animal, the latter is the ruminant. In the absence of natural or artificial dentures mastication with the gums may be efficacious, and asylums for the aged are said to present many complete edentates who show remarkably good nutrition. At the present day the statement is often heard that the edentate has his compensations in absence of disease from focal infection about tooth sockets.

The *Journal de Médecine et de Chirurgie Pratiques* for January 10 contains an abstract from an article by Mollière on the dyspepsia of the edentate soldier. It does not appear that a complete loss of teeth is suggested, for the statement is made that 15 per cent of all the French troops have dental insufficiency. These are divided into two great groups, the ante-bellum and post-bellum. The former consist chiefly of peasants who are normally almost vegetarians and have the habit of slow mastication. As soon as these men entered upon a diet of cold meats and canned foods they tended to develop gastroenteric infections and many evacuations from the front became necessary. Those with plate teeth escaped these accidents for a time but sooner or later the dentures were broken and they joined the ranks of the other edentates. The post-bellum or propter-bellum type differs radically from the preceding class and comprises those wounded in the jaws, and in greater numbers those who shed their teeth or require numerous extractions.

The author now analyzes three types of dyspeptic, viz., the food bolter, the undernourished, and the infected. The bolter or tachyphagic as a rule comes into evidence after he has been ill or wounded and is convalescent on a liberal regimen. Habitually a large and rapid feeder, he develops a familiar form of indigestion from incorrect eating. It often happens that he had suffered from this evil before the war and had improved on the war diet. An artificial denture alone will not cure these subjects, who must be taught the correct manner of eating. Of the undernourished type it need only be said that in addition to dental insufficiency there is often a deep repugnance to the diet which consists so largely of cold food. Anorexia and debility set in, and the men form an easy prey to typhoid and paratyphoid infections. There is naturally much constipation in this type.

The infected subject, unlike the others mentioned, does not complain much of his stomach. His mouth is badly infected and he is addicted to pipe smoking. Pus in the pyorrhea subjects is constantly swallowed with the saliva. The men seldom report sick and the extraction of roots followed by perox-

ide gargles often causes much improvement. For some unknown reason they do not bolt their food, but habitually chew slowly, which explains their freedom from many symptoms of indigestion.

The above classification works well in practice and for five months Mollière has carried out a definite plan. First he strives to make painless mastication possible. Peroxide mouth washes are used and ulcerated gums are touched with chromic acid 1-500. The men must chew by habit to harden their toothless gums, incidentally also as a preparation for wearing a plate. The soups and pul-taceous foods discourage mastication which must nevertheless be kept up; and the victims are therefore as far as possible given such food as requires mastication. Excellent for this purpose are the legumes; they are soft, yet require chewing because they cannot, so to speak, dissolve in the mouth. Once provided with dentures the men resume their full regimen of fresh meat, cereals, legumes, bacon, etc. Cereals and potatoes made into small balls, green legumes, and a hash of meat form a good ration. On account of lack of oil and vinegar for salads the ordinary salad vegetables may be hashed up with the meat.

The man who does not masticate well or naturally suffers from a defect of saliva requires something pungent to provoke a flow of the latter. In addition to ordinary condiments onions or kitchen herbs, such as thyme, are useful. An insipid diet is not good for soldiers. Among drugs rhubarb and soda mixtures and arsenic are the best stomachics. Calomel and salines, with rarely opiates, are the chief drugs for intestinal disorders.

Reeducation of the Disabled Soldier.—In *Recalled to Life*, No. 2, 1917, is a description of what is being done for the Canadian disabled soldier. The author of the article says that the French, as usual, were the first to discover the principle upon which disabled soldiers should be returned to civil life. To each one must be assured the possibility of earning his own livelihood, by helping him so that in the end he will require no further help. There is an analogy between the case of the child and the disabled soldier. Both require to be educated and supported until they can support themselves. The principle has been accepted in Canada, and it has been elaborated into four postulates by Major J. L. Todd of the Canadian A. M. C., who is working indefatigably so that correct methods may prevail: (1) Bodily or mental disability due to military service must be brought to an irreducible minimum. (2) When necessary and possible, disabled soldiers must be taught an occupation, so that they may become employable. (3) If necessary, they must be assisted to obtain employment. (4) Pensions will vary in accordance with the extent of the disability in respect of which they are awarded.

Unless these postulates are understood and accepted there will be the political danger that the discharged soldiers band themselves together as voters and make claims upon the treasury greater than can be borne. In the United States the pension bill amounts to \$200,000,000 a year, although it is fifty years since the Civil War. In Canada, one-seventh of the adult male population will have seen

military service, and it is not probable that they will conspire politically against themselves, since in the end they must pay the bill. The disabled cannot learn too soon that they must do what they can to help themselves, and that they must display in time of peace the same courage which supported them in time of war. Under present arrangements a Canadian soldier totally disabled receives a pension of \$2,500 a year. If he is so severely injured as to require an attendant, he may receive an additional \$200. For each of his children he is allowed \$75. Pensions are, under the warrant, unaffected by the man's earning power, income, or social position; they vary in accordance with the rank, but not according to the length of service. This uniformity of pensions does not afford so great an inducement to refrain from acquiring a new occupation as would at first sight appear. The degree of disability is estimated by a Board of Commissioners, and they take into account a man's capacity, apart from the inclination for acquiring a new trade, or practising a trade he had already acquired. They estimate his value in the labor market, and supply the deficiency which will bring him up to the standard. His pension is not diminished if he works; it is not increased if he elects to remain idle. Arrangements are in progress for settling upon the land all returned soldiers. The terms are very liberal. The man is given free 160 acres of land, and he may receive upon loan as much as \$2,500. Work upon the land is not incompatible with a fairly high degree of physical disability, provided intelligence is present by way of compensation.

The policy of Surgeon-General Foster, director of Medical Services in the Canadian Military Forces Overseas, is to return to Canada as quickly as possible all casualties who are not reasonably likely to become efficient within six months. The hospitals in England are thereby relieved. These men will undergo further treatment in Canada, and when necessary they will have an opportunity for reeducation, and so be absorbed into civil life. It is only to a moderate extent that reeducation is practised in Canadian hospitals in England, and in such cases it is a part of the medical treatment which is intended to fit the man for the army rather than immediately for civil life. It has been found the best practice to separate hospital treatment from industrial reeducation. When the hospital has done its best for a man he should be discharged to a convalescent or training camp. Such work as is required under this policy is done at Granville Canadian Special Hospital, Ramsgate. The methods employed in the hospital are curative rather than vocational; but being curative does not prevent them from being vocational also. Cure leads to vocation. Every new movement that is acquired will be of value later in life, no matter what calling the man elects to follow. A patient with a partially ankylosed wrist is set to work using a hammer. If the elbow or shoulder is involved he is given a saw; if the fingers are involved he will be assigned to some task in which the use of finer and more complicated tools is required. Obviously, if a man will continue to use only these separate tools, presently he finds himself acquiring some knowledge of carpentry; and as there is a natural dislike for purposeless work, he soon directs his energy to

works of utility. Insensibly the hospital department becomes a workshop and the patient a mechanic.

Suggested Mobilization of the Entire Medical Profession.—For the purpose of completing the mobilization of the entire medical and surgical resources of the country, the Council of National Defense has authorized and directed the organization of a "Volunteer Medical Service Corps" which is aimed to enlist in the general war-winning program all reputable physicians and surgeons who are not eligible to membership in the Medical Officers' Reserve Corps. Slight physical infirmities, or the fact that one is beyond the age limit, fifty-five years, or the fact that one is needed for essential public or institutional service, while precluding active work in camp or field or hospital in the war zone, should not prevent patriotic physicians from close relation with governmental needs at this time. It is intended that this new corps shall be an instrument able directly to meet such civil and military needs as are not already provided for. It is proposed that the services rendered by the Volunteer Medical Service Corps shall be in response to a request from the Surgeon General of the Army, the Surgeon General of the Navy, the Surgeon General of the Public Health Service, or other duly authorized departments or associations, the general administration of the corps to be vested in a central governing board, which is to be a committee of the General Medical Board of the Council of National Defense. The State Committee of the Medical Section of the Council of National Defense constitutes the governing board in each State. It is proposed that physicians intending to join shall apply by letter to the secretary of the Central Governing Board, who will send the applicant a printed form the filling out of which will permit ready classification according to training and experience. An appropriate button or badge is to be adopted as official insignia.

Hospitals and the War.—In December, 1917, a questionnaire was sent by the New York State Council of National Defense, Medical Section, to three hundred and seven institutions listed as hospitals of the State of New York in the 1917 Medical Directory of New York, New Jersey, and Connecticut. One hundred and seventy-three replies only were received, but of these 167 contained sufficient information to compute the commissioned percentage of the total staff. These replies show that the average percentage of attendance commissioned is 22.5; that of internes is 53.8. There are 18 hospitals that have 50 per cent. or more commissioned; 45 hospitals have between 25 and 50 per cent. commissioned; 105 have less than 25 per cent. commissioned, and 22 hospitals have no staff members commissioned. Seventy-one hospitals state that the present staff is more than sufficient for civilian needs and that additional members of attending staffs can be spared if needed for military service. Sixty-one hospitals state that they have enough, but can spare none additional for military service. Thirty-five hospitals state that present staff is insufficient for civilian needs. Forty-six hospitals were caring for officers or enlisted men at the time of replying, or had recently been doing so. A majority, but not all of those commissioned are in the

Medical Reserve Corps. Membership in the Medical Corps of the Army, Navy, National Army, National Guard, and State Guard, the Naval Reserves, and Naval Militia, is also represented. As a result of this investigation the following conclusions have been formulated: "The response of the hospitals to the call of the national emergency has been, for the most part, highly patriotic. In general, they have not suffered any real loss of efficiency by so doing, but in certain instances individual hospitals have lost efficiency by losing too large a percentage of men commissioned. Certain additional members can be spared from the staffs of selected institutions without injury to them or their public service. The selection of these additional members should be made with great care."

Philadelphia School of Neurological Surgery.—A third course in neurological surgery, under the direction of the Surgeon General's office, has been started in Philadelphia, and is now being given at the Jefferson, Philadelphia General, and University hospitals. The course has been arranged especially for the instruction of Medical Reserve officers to whom will be assigned the care of those suffering from injuries to head and spine. It covers a period of ten weeks, with 31 hours of work a week, and includes demonstrations, lectures, clinics, and quizzes. The anatomy, physiology, and pathology of the nervous system are thoroughly studied under specialists in these branches. Ophthalmologists and otologists give lectures on the relation of the eye and ear to nerve surgery. The latest developments in the science of the use of the x-ray are demonstrated. Clinical neurology, from the standpoint particularly of localization of lesions and projectiles, is taught. Lectures on army administration are given weekly. The serology of the cerebrospinal fluid is dealt with in detail, and opportunity for laboratory examination is given the student officers. Operative clinics are held 8 hours a week at the University and Jefferson hospitals, and special lectures by authorities from other cities are arranged for from time to time. The director of the school is Dr. Charles H. Frazier, and the adjutant is Capt. Thomas M. Joyce. Its headquarters are located at the University Hospital.

Program for the Rehabilitation of Disabled Soldiers.—A conference was called in Washington on January 14, 1918, under instructions from the War Department, at which the Surgeon General presented a program worked out by the Surgeon General's office, providing for a comprehensive system of reconstruction, medical and economic, to be carried on under military auspices. The other conferees urged that, while medical and surgical repair was granted to be within the scope of the surgeon's work, vocational training was a civilian matter, and should be given under civilian auspices. It was argued that the after care of the disabled soldier was already intrusted by Congress in some degree to the Bureau of War Risk Insurance, and that several other governmental departments had in the matter very definite interests and responsibilities. After considerable discussion the matter was referred to a committee, which was instructed to draw up definite recommendations regarding the program to be adopted. This committee, on January 21, presented a bill for submission to Congress calling for

the creation of an interdepartmental commission to be known as the "Board of Vocational Rehabilitation." This bill is now being introduced into Congress. The bill provides that the Board of Rehabilitation shall be composed of one representative respectively of the Department of the Treasury, Department of War, Department of Navy, Department of Labor, and Federal Board for Vocational Education. Under the provisions of this proposed bill every person disabled in the military or naval service shall, upon order of the Bureau of War Risk Insurance, follow such course or courses of vocational rehabilitation as the act prescribes and provides. This, however, does not apply to such persons as are able, in the opinion of the Bureau to resume their former occupations. Section 7 of this bill provides "that all medical or surgical work or other treatment necessary to give, as far as possible, functional and mental restoration to disabled persons in the military service, shall, prior to their discharge from such service, be directly under the executive control of the War Department and the Surgeon General's office of that department; all such work or other treatment necessary to give functional and mental restoration to disabled persons in the naval service shall, prior to their discharge from such service, be under the executive control of the Navy Department and the Bureau of Medicine and Surgery of that department, and all such work or treatment necessary to give functional or mental restoration to disabled persons who have been discharged from the United States military and naval service and require further treatment, shall be under the executive control of the War Risk Insurance Bureau. Whenever prevocational training or other work, mental and manual, is employed by the office of the Surgeon General of the Army, by the Bureau of Medicine and Surgery of the Navy, or by the War Risk Insurance Bureau, as a therapeutic measure, a plan shall be arranged between each of these agencies and the Board of Vocational Rehabilitation, acting in an advisory capacity, to insure in so far as medical requirements permit, a continuous process of prevocational training and the proper preparation of instructors for such training." The bill further provides that the Board of Vocational Rehabilitation be empowered to receive gifts and donations from public or private sources and to expend the same in carrying out the purposes of this act, and calls on Congress for an appropriation of \$10,000,000. Upon request of the United States Employees' Compensation Commission, such vocational rehabilitation shall be made available without cost for instruction for the benefit of any civil employee of the United States disabled while in the performance of his duty, and it may be made available, in the discretion of the board, for the benefit of any other person disabled in the course of employment or otherwise, if requested by any State compensation board or other State organization, or by any corporation, association, firm, or individual.

Lower Death Rate and Improved Health in Camps.—Reports from the officers of the Surgeon General for the week ended February 15 show a lower death rate in all the camps than for any other week since last November. Deaths in all camps, Regular Army, National Guard, and National

Army, totaled 177, of which 96 resulted from pneumonia. There were fewer cases of serious illness reported than for the preceding week. The regulars showed the highest death rate, 12.9 in a thousand per annum, and their non-effective and admission rates showed slight increases over the preceding week.

Deaths at Aviation Schools.—The War Department has issued a statement in response to inquiries regarding the risks of aviators in the service, showing that from the beginning of training, in June, 1917, to date, the fatalities at military aviation fields in this country have numbered 51. Since the training of aviators began, student aviators have flown considerably more than 100,000 miles, averaging about 1,700 hours of flying daily. Considering the number of men learning aviation and the amount of flying, the percentage of fatal accidents is remarkably low.

Mobile Optical Shops for France.—Large automobile trucks, each containing the equipment of a well-appointed optical workshop, are soon to be put into service in France. From the men obtained in the first draft, those skilled in optical lines were ordered to Fort Sill, Okla., to await the completion of the plans and the procuring of the required machinery, tools, and the large stock of optical glass that will form the first equipment of the plants. The main shop from which the mobile units will be operated will be able to turn out 200 pairs of glasses a day on prescription.

New Plan to Train the Unfit for Service.—A new movement has been launched by the National Security League, headed by Walter Camp, for the physical upbuilding of those men who have been found unfit for military service. The plan has the approval of Raymond B. Fosdick, chairman of the War and Navy Departments Commission on Training Camp Activities. The mayors of 5,000 cities and towns have been asked to cooperate. The propaganda of the movement states that the physical reserve of the nation cannot be rallied in a moment unless it has been upbuilt by years of habitual physical exercise of the kind that will keep the human engine in working condition. The object of the present movement is to supply this want by a simple program of exercise suitable for every man and every woman who has the will to undertake it.

Cooperation Between Army Officers and Red Cross.—The War Department has ordered full cooperation between army officers and the Red Cross. Officers have been ordered to inform troops of the presence of the Red Cross representatives and their willingness to help soldiers or their families. Red Cross representatives are authorized to be attached to each base hospital, to furnish emergency supplies, to communicate with the families of patients, and to render any other service for patients.

American Ambulances Again Honored.—The American Ambulance, its founders, and its work, have again been signally honored by the French government. Laurence V. Benet of Washington, one of the organizers of the ambulance, has been promoted from officer to commander of the Legion of Honor. Eugene A. Lachaise of New York, now second in command of the American sections, has been promoted from chevalier to officer of the Legion of Honor.

Navy to Care for Wounded.—As the result of an agreement reached by Secretaries Baker and Daniels, Admiral Benson, and Surgeon General Braisted, the care of sick and wounded soldiers aboard transports returning from France will be undertaken by the Navy Medical Corps, since the Navy already maintains a hospital service aboard such vessels.

Athletic Directors to Accompany Soldiers.—Athletic directors who have received army commissions will accompany the troops to France. The Commission on Training Camp Activities, in making this announcement, said that boxing instructors would not accompany the troops to the other side, as they are believed to be of greater service in the home camps.

Red Cross Farm in France.—A 500-acre farm near Tours, France, has been acquired by the American Red Cross, which is to be used for the education of crippled French soldiers. At the school the soldiers are to be taught how to use farm machinery. In speaking of the reeducation of maimed men, Maj. James H. Perkins of the Red Cross Commission in Europe stated that the professions which offer the greatest appeal to disabled men are industrial drafting and design, making surgical instruments, watch-making, etc.

Attempted Air Raid on American Hospital.—A despatch to the Associated Press, under date of February 16, states that an American field hospital in a town within our lines was apparently a target for German shells. Two sets of bombs were dropped, and although the hospital and the residents of the town were severely shaken up no damage was done.

Dr. Bertha Tallant, the Medical Director of the Smith College Hospital Unit in France, has just returned from the evacuated part of that country, where the unit is working. Dr. Tallant, in describing conditions of medical practice there, states that they are much the same as those in which a country doctor finds himself who has a practice within a thirty-mile radius.

Dr. William Palmer Lucas, chief of the Children's Division of the American Red Cross, together with several doctors and women workers, left Paris on February 16 for Marty, to study conditions in that locality preparatory to giving financial aid and other assistance.

Deaths in the Service.—Dr. FRANK HARRIS GARDNER of Montrose, Pa., First Lieutenant, M. R. C., U. S. A., died of pneumonia on February 23. He was on duty at the Government reservation in Hoboken, having been ordered there six weeks ago from Fort Oglethorpe, Ga. He was 28 years old, and was graduated from Jefferson Medical College in 1916.

Dr. DUDLEY W. QUEEN of Temple, Texas, a member of the Medical Corps, U. S. N., R. F., died two months ago in England of meningitis. He was on a torpedo boat operating against the submarines off the English coast. He was born in Williamson County, Texas, in 1886.

Dr. MILTON J. LICHTY of Cleveland, Ohio, Captain M. R. C., U. S. A., died on February 15 at Camp Taylor, Ky. He was born in 1869, and was a graduate of the Medical Department of the University of Pennsylvania in the class of 1895.

MEDICAL RECORD.

New York, March 2, 1918.

POSTOPERATIVE PULMONARY COMPLICATIONS.

THE actual frequency with which postoperative pulmonary complications occur is not generally appreciated, and this for two reasons: first, because the majority of such cases are not reported; and, second, because the milder grades of postoperative affections of the lungs, bronchi, and pleuræ are often not even recognized. Two careful studies of postoperative pulmonic complications have recently appeared: one, by Cutler and Morton (*Surgery, Gynecology, and Obstetrics*, December, 1917), is based upon the records of 3,490 patients operated upon at the Massachusetts General Hospital from July, 1915, to July, 1916; the other, by Whipple (*Surgery, Gynecology, and Obstetrics*, January, 1918), is based upon the records of 3,719 patients operated upon at the Presbyterian Hospital of New York during the years 1915 and 1916.

In Cutler and Morton's series there were postoperative pulmonary complications in 65 cases, classified as follows: Lobar pneumonia, 19 cases; bronchopneumonia, 21; bronchitis, 7; pleurisy, 5; empyema, 2; mediastinitis, 3; pulmonary embolism, 6; pneumothorax, 2. The authors are sure that a number of cases of bronchitis or transient pleurisy escaped mention in the hospital records through not being sufficiently recorded in the postoperative notes. Each of the conditions noted in the above enumeration is discussed *in extenso*, not only with reference to their own cases, methods, and opinions, but also in the light of a review of the literature, with the incorporation of statistical tables.

Cutler and Morton think that the anesthesia *per se* has, as a rule, been unjustly blamed for the occurrence of postoperative pneumonia and that there are other factors of far greater importance. The figures presented from their clinic show that one in every 54 cases operated upon in the course of a year developed a postoperative lung condition, and that one in every 106 died; and the authors suggest that this should be a sufficient warning to make any surgeon consider thoroughly all the risks involved and what precautionary methods he might use in each and every case. In their opinion the predisposing factors are: (1) Poor general condi-

tion, *i.e.* age, anemia, alcoholism, arteriosclerosis, weak heart, or susceptible lungs. (2) Oral sepsis. (3) Preexisting lung disease—not only tuberculosis, but bronchitis, emphysema, or a recent pneumonia. (4) Anesthetic badly given. (5)* The presence of septic foci. (6) Too radical operations that open up pathways to the neighborhood of the lungs or to the lungs themselves. (7) Operations in the epigastrium in which there is danger of vascular or lymphatic extension. (8) Exposure to cooling fluids or to draughts (vasomotor disturbance). (9) Postoperative pain resulting in hypostasis from poor expansion. This list of the predisposing factors suggests the prophylactic measures.

Whipple's article deals with postoperative pneumonitis only, of which 97 cases occurred in 3,719 operations or 2.3 per cent. Like Cutler and Morton, he finds that the anesthetic itself has little to do with the incidence of this complication. Indeed, for the years 1915 and 1916 the relative percentage of cases in which pneumonitis developed after local anesthesia by novocaine was greater than when ether or gas-oxygen was used.

Whipple groups the predisposing factors under the following headings: Local inflammations in the upper respiratory tract and factors favoring them; vasomotor changes causing a congestion of the pulmonary vessels; factors inhibiting the normal thoracic and abdominal respiratory movements and favoring atelectasis and hypostasis in the lung; local or general infections elsewhere than in the respiratory tract; debilitated states resulting in a lowered natural or acquired immunity to the particular organism inciting pneumonia, and factors increasing the virulence of the inciting organisms. Regarding the immediate inciting cause, Whipple says that it is generally accepted that there is an inciting cause in the form of some microorganism in every case of fibrous or croupous pneumonia, and that this probably holds as true in the so-called postoperative pneumonia or surgical pneumonitis. Considerable space is given to the discussion of the four pneumococcus groups. The first three of these, he says, may be called parasitic inasmuch as they are not found in the normal throat; while the fourth, or heterogenous group, is saprophytic in the throats of normal individuals, and is found in perhaps 60 per cent. of throats. He thinks it justifiable to consider the Group IV pneumococcus, the inciting factor in the majority of postoperative pneumonias; while the fatal cases are usually due to pneumococci of the first three groups or are embolic pneumonias.

Among Whipple's conclusions are that postoperative pneumonitis is a far more frequent complication than is acknowledged or reported; that its incidence in surgical services varies largely with the care given to its detection, for many of these pneumonias are overlooked under the term "postoperative reaction"; that the pneumonitis caused by pneumococcus IV is, as a rule, an atypical pneumonia of short duration, resolving by lysis, and has

a lower mortality than the groups I, II, and III pneumonias or the pyogenic or septic types; and that the x-ray is a valuable aid in the early diagnosis of lung complication, for the lung shadow usually appears in the radiogram before frank signs of consolidation can be elicited.

It will be seen that there are a number of points of similarity in these two articles. The authors agree that the anesthetic itself has been given far more than its due share of prominence as an etiological factor; and that with the exercise of proper care many of the causative factors can be eliminated. Many cases of postoperative pneumonia occur each year through ill-advised or inopportune operating. In some instances the fault may lie with the operator; while in others it may be due to neglect on the part of the house surgeon to call the operator's attention to conditions that would contraindicate immediate operation except, of course, in cases of real emergency. The actual percentage in which severe postoperative pulmonic complications occur is fortunately small, and for that very reason surgeons and members of house staffs have not infrequently been led to disregard slight affections of the upper respiratory tract and to neglect easily taken precautions. This is especially apt to occur when postponement of operation would cause inconvenience.

DISEASES DUE TO DEFECTIVE ALIMENTATION.

In the widest significance of the term defective alimentation is responsible for the great epidemics such as follow in the wake of famine. Here belongs typhus fever. In the more restricted sense, with reference to deprivation of special classes of food, we have the triad pellagra, scorbutus, and beriberi. There are other more insidious affections affiliated in some way with insufficient nutriment—polyneuritis, hemeralopia, anemia, hemophilia, and last but not least tuberculosis. Certain hitherto unknown maladies—forms of edema, etc.—are believed to be due to the same causes, and in a general way lack of nourishment doubtless modifies many affections and even to some extent favorably. This we see in affections in which underfeeding is indicated and which do not here further concern us. Pellagra is the most widely diffused, most common, and at present the best known disease of defective alimentation, having in this respect displaced the medieval scorbutus, which persists in certain forms. But these affections, as well as beriberi, are too well known to require description.

In 1871 during the last weeks of the siege of Paris the mortality decupled from weakened resistance to disease. The people developed a special predisposition to acute infectious diseases, acute bronchitis, congestions, and hemorrhages—especially of the lungs and intestines. Pneumonias, which were common, suggested the secondary, complicating type, such as occurs sometimes in malaria; while the diarrheas were also changed in

type, resembling tropical forms and chronic dysentery.

These data are taken from an article by Plicque in the *Journal de médecine et de chirurgie pratiques* for November 10. A fact of interest in connection with polyneuritis is that this malady does not occur alone in beriberi, but to some degree in inanition and general denutrition. It sometimes precedes cachectic states. In neurasthenia there is also a food-deficiency factor as shown incidentally by the presence of emaciation. The singular prevalence of hemeralopia in the present war has been definitely traced to defective and insufficient regimen. Moreover, it is known to accompany scurvy and pellagra. It occurs in epidemic incidence in prisons, convents, etc., in times of penury and want.

There are definite psychoses due to food scarcity in association with psychic causes and alcoholism. These are akin to the subdelirium of starvation, and suicide is not uncommon. Such psychoses recall in a measure the psychic component and suicidal tendencies in beriberi. The relations of chloroanemia and tuberculosis to deficient nourishment are too well known to require discussion.

Along with deficiency diseases the underfed suffer from alimentary intoxications of various kinds due to unhygienic foods. Substitutes often disagree with digestion; saccharin, for instance, causes gastralgia, anorexia, nausea, and diarrhea; it suggests that while in the mood one might seek to replace diet sugar with sugar of lead because this salt happens to be sweet. The various additions to bread grains in bread making, to say nothing of adulterations and complete substitutes, have in the past been responsible for ergotism and lathyrism, and some of the warm breads have caused much digestive disturbance.

GRADUATION THESES OF PROMINENT MEDICAL MEN.

A RESEARCH into the subject of the inaugural dissertations and graduation theses of great physicians and surgeons of the various enlightened nations brings out the somewhat curious fact that in at least one-half of the cases the men could have had not the slightest inkling of their approaching spheres of professional activity. In certain classes of practitioner, notably laboratory men and alienists, the career was usually foreshadowed by the thesis. The student of the former class commonly entered the laboratory as an assistant to his professor and wrote his thesis at the latter's suggestion and under his guidance; often enough he remained in the laboratory, was promoted to chief assistant and ultimately through the death or transfer of his superior became professor. This seems to have been the lot of the anatomist, physiologist, medical chemist, and pathologist. It is not so apparent why the same custom should obtain among alienists, but to go no further, Esquirol, Moreau, S. Pinel, Bailarger, Billod, and Magnan, all well known later as alienists, wrote theses on insanity or brain disease.

Among the great clinicians, surgeons, internists, and specialists, such a sequence seems to have been the exception. It is true that Brehmer wrote on the laws of consumption, and Unna on the development of the skin; that Bilharz, while a student, wrote on blood parasites, and Lepine, while an undergraduate, wrote on the animal sugar ferment. Israel, the famous renal surgeon, wrote on nephritis, but his subject was medical nephritis. Brand did not write on typhoid fever or analogous theme, but on pyloric stenosis. The thesis of Brieger on gangrene of the lungs was not so remote as a subject from that of ptomaines. Bouchard, so well known later for his work on autointoxication, took apoplexy for his subject.

But the great syphilographer Fournier wrote a very unpretentious thesis on uremia before chance made him Ricord's assistant. The equally illustrious Neisser wrote on echinococcus disease and enlarged his thesis into a classic. Behrend, who became distinguished as a dermatologist and syphilographer and edited the earliest periodical devoted to these subjects, wrote his thesis on the vision of the mole. Hoffa, the orthopedist, wrote on lead poisoning, and Bardenhauer, the surgeon, on premature birth. Cavazzini, an Italian surgeon, took for his subject locomotor ataxia. Loeffler did not write on diphtheria or kindred subject, but on bloodletting. Ziemssen, who later edited a system of medicine, had for his maiden effort hospital gangrene, and Madelung wrote on tartar emetic in psychoses. Jourdan, who became highly eminent as a pharmacist, wrote on pellagra. Haslund, the Danish dermatologist, wrote on rhinoscopy, and Koebner, also a dermatologist, on cane sugar digestion. Schultze, of obstetrical renown, wrote on pathological fat formation. Hardy, distinguished internist and dermatologist, took the commonplace of cautery of the cervix. Even the great Virchow found no better subject than "Rheuma, Especially of the Cornea." The equally great Boerhaave foreshadowed his future in a fine dissertation on the "Utility of Exploring the Secretions" for the purpose of diagnosis, while Rush was happy in his choice as a subject of stomach digestion. Haller wrote appropriately of the newly described Coschwitz's duct and Jaeger of cataract. Mesmer chose astrology as his theme, and Kaltschmidt, who became a famous operator on cancer, wrote his thesis on "Cancer, Especially of the Breast." On the whole, however, our proposition will be found to hold good that at least the half of our leaders in medicine had no insight into the nature of their future spheres of action.

ALLEGED CURABILITY OF OZENA.

DESPITE the work of the bacteriologists and the evidence that at least the odor of ozena is the product of a specific type of bacteria; despite the generally accepted teaching that ozena can be controlled but never cured, Duverger (*Revue de laryngologie, d'otologie, etc.*, January 10) denies both propositions when he asserts that the disease is neither

microbic in origin nor incurable—in fact, he claims that it is readily cured and is, as diseases go, rather more amenable to treatment than most others. The author insists that ozena represents a local manifestation of constitutional inferiority. The insufficiency of the mucosa leads to its atrophy, and the bony structures as a consequence themselves become atrophic. The physiological stimulant of the mucosa, or rather of its secreting crypts, is air; and in a subject under 30 years nasal respiration will, when systematically and persistently carried out, effect a cure. The crusts must be removed, but never by lavage; atomization with the mineral oils and a little massage are sufficient for the purpose. The patient must breathe through his nose during his sleep, and as he cannot do this voluntarily some retentive apparatus suggests itself. The general health must be built up and subjects who can live out of doors do better than the sedentary. The author's success in the treatment of ozena is possibly due largely to the fact that he practises in Cairo, in a climate in which certain chronic ailments greatly benefit—tuberculosis and nephritis, for example. The extreme dryness of the air should increase the tendency to the formation of crusts, and the author warns against all procedures which tend to stimulate the production of nasal secretions. He states that the Arabs are remarkably free from ozena, although he naturally scouts the idea that this is due to their dislike of the dog, claimed by Perez to be a carrier of the ozena bacillus.

ASSOCIATION OF ADENOID VEGETATIONS WITH PHIMOSIS.

A COINCIDENCE not fully appreciated is the frequent association of these two affections which appears to be somewhat baffling to certain writers, for while phimosis is a congenital malformation, adenoids is generally regarded as an acquired condition although possibly itself due in part to a congenital narrowing of the nasal chambers. Either condition seems able to cause urinary incontinence. Recently Lasalle wrote an article on this subject, which is abstracted in the *Journal de médecine et de chirurgie pratiques* for December 10. Within a brief interval he was summoned to treat cases of urinary incontinence in three small boys. In each patient he found both phimosis and adenoids. In two both operations—circumcision and adenoidectomy—were at once performed and incontinence immediately ceased. In the third only circumcision was performed and the incontinence continued unchecked. The French author, not himself a rhinologist, appears to regard adenoids as inevitably a primary manifestation of disease; but certain others regard it as, in part, secondary to congenital insufficiency of the nasal passages. It seems at present impossible to connect a condition like phimosis embryologically with defective osseous development of the bones of the nasal chambers, and the physiological association between the nasal mucosa and sexual apparatus does not assist us here. That two such very common conditions should occasionally, or even frequently, coexist ought not, however, to be surprising, and it is possible, or even probable, that the only relation between the two conditions is one of coincidence.

A SIGN OF BEGINNING INSUFFICIENCY OF THE CIRCULATION.

A TRUSTWORTHY token of the mildest degree of circulatory failure has long been the quest of the internist, and the number of induced tests described rather goes to show that spontaneous evidences are still far to seek. Galli, in a short article published in *Il Policlinico*, for January 13, refers first to Krehl's minimal edema which appears in the feet if the patient is up and about and over the sacrum if he is in bed. The author thinks the precordium the best region to test from this viewpoint. Even the persistent mark made by the stethoscope in listening for the heart sounds may indicate an edematous condition of the skin due to circulatory insufficiency. If now the ring of the stethoscope be pressed over the tibia or malleoli no such persistent imprint appears, and this is true of the rest of the surface. The presence of a trace of edema over the heart cannot, of course, depend in any way upon the force of gravity but upon uncomplicated stasis of purely mechanical, *vis a tergo* type. Absence of contracting muscle over the sternum and precordium in general is believed to be an important factor, and the respiratory rhythm, with the continuous alternation of intrathoracic pressure, is another factor to be considered, both favoring the lymph stasis, which gives rise to the edema. The principal drawback to the test is that it does not bear alone on cardiopathies, but may be positive in any condition of general debility, in which, naturally, circulatory force must suffer.

News of the Week.

Pneumonic Plague Menaces North China.—According to advices received by the American Board of Commissioners for Foreign Missions from staff members in north China, the plague has broken out in its pneumonic form in Shansi Province, China, and has assumed such proportions that all north China is seriously threatened.

America Outdoing Germany in Chemical Products.—In a report recently made public by Professor D. D. Jackson of Columbia University the statement is made that with proper legislation this country can compete with any other nation, including Germany, in the manufacture of chemicals, whether for purposes of war or peace. The war has given a great impetus to the manufacture in this country of photographic developers, lenses, pharmaceuticals, synthetic perfumes, flavoring extracts, saccharine, and many other products. We are now able to make our own laboratory glassware of a quality superior to that of Germany or Austria. Our plants are now producing phenol in large quantities, while before the war every pound of synthetic phenol came from Europe.

A Waste of Food That Should Be Prevented.—A recent bulletin of the New York City Department of Health calls attention to its work of protecting the consumer in this city against spoiled or otherwise unwholesome food by condemning large quantities of food each week. Much of this condemned food could by prompt and proper handling be salvaged. At times considerable portions of condemned foods are still fit to be used as food, but under

present mercantile arrangements it does not pay to pick it over and salvage it. During January alone considerably over \$500,000 worth of food was condemned and destroyed. There is a crying need for some plan whereby such food could be picked over promptly, cooked and dried under administrative control, thereby converting some of it into wholesome human food, and practically all the rest into food for animals.

New York Renews Fight Against Jersey Factory Fumes.—The Board of Estimate of New York City, on February 21, instructed the corporation counsel and the health commissioner to intervene in the fight the West End Association is making before the State Board of Health to put a stop to the nuisance caused by the acid and gas fumes from chemical works along the Jersey shore. The offending chemical companies are to appear before the State Board of Health in summary proceedings on March 2 to show cause why their charters in this State should not be revoked. This action is taken under the recent act of the Legislature which permits the State Board of Health to revoke the New York State charter of a corporation whose plant, located outside of the State, constitutes a nuisance to residents of New York State.

Health Board Extends New Plan.—Hereafter in the boroughs of the Bronx and Queens the responsibility for most of the administrative work of the Health Department will rest with the assistant sanitary superintendent. Dr. Arthur J. O'Leary has been appointed assistant sanitary superintendent to the Bronx, and Dr. John Barry will continue to hold that office in Queens. These changes are made in accordance with the policy of bringing the department close to the people, practically giving each borough autonomy in all local matters.

Deaths from Pneumonia Decrease in New York.—The report given out by the Health Department for the week ending February 23 is more encouraging as regards the pneumonia situation. For the week ending February 23, 1,570 deaths occurred from all causes, and 312 of these were from pneumonia; for the week ending February 16 there were 1,738 deaths, of which 373 were from pneumonia.

Doctors Held for Selling Narcotics.—As the result of information obtained by a surgeon in the United States Navy from a sailor who had been obtaining drugs, four doctors were arrested and arraigned before United States Commissioner Hitchcock. The names of these doctors are A. A. Robert Bankowsky, Ira E. Booth, John L. Corish, and M. A. Di Preta. The name of only the first of these is in the Medical Directory of the State of New York, so it is probable that the others are not licensed practitioners of medicine.

The "Archives Médicales Belges" is just entering upon the second year of its resuscitation under the editorial supervision of the Belgian army surgeons. The revival of this excellent journal in the midst of the labor and fatigue of the war bears witness to the indomitable spirit of this brave and sorely afflicted nation.

Birth Control Case Again Appealed.—Mrs. Margaret Sangster, who was convicted in the lower courts of violating the section of the penal code prohibiting the dissemination of birth-control information and paraphernalia, and who then carried

her case to the Supreme Court of New York State, and again lost, has now appealed to the Supreme Court of the United States.

Value of Antenatal Work.—A recent publication of the New York City Health Department gives detailed statistics covering three years of antenatal work in a section of the city selected for the purpose of demonstrating the effect of this kind of public health work. There were in this district in 1914, after the inauguration of antenatal work, 869 living births, with 17 deaths during the first month of life, or a rate of 19.5 per 1,000 living births, as compared with the rate for the city as a whole of 36.6. In this district, in 1917, there were 1501 living infants, among whom there were 22 deaths during the first month, or a death rate of 14.6 as compared with the city rate per 1,000 living births of 35.3. It is believed that these figures bespeak the value of antenatal work and make an extension of this activity most desirable.

A Lecture on Health Conditions in France.—A meeting will be held at the New York Academy of Medicine on March 13, 1918, at 8.15 P. M., under the auspices of the Public Health Committee. The lecture, illustrated by lantern slides, will be on "Health Conditions in France and America's Effort to Aid Them," and will be given by Dr. James Alex Miller, recently returned from France.

Dr. J. W. Reed of Ocean View, Va., has been elected health officer of Norfolk County, Va., and **Dr. George M. Converse** of the Public Health Service has been appointed director of health affairs for the county.

Dr. George Gray Ward, Jr., Professor of Gynecology at Cornell University Medical College, has been appointed chief surgeon and surgical director of the Woman's Hospital, New York, to succeed **Dr. Clement Cleveland**, who has resigned.

Surgeon General Sir Alfred Keogh has retired from the British army to resume his work as general executive officer of the Imperial College of Science and Technology. He will be replaced by **Colonel Goodwin**.

Gifts and Bequests.—Announcement was made on February 22, Alumni Day at Yale, that the Carnegie Corporation has made a gift of \$250,000 to the Yale Medical School and one of \$25,000 to the Yale Mobile Hospital Unit.

The New Hampshire Memorial Hospital at Concord, N. H., has opened a new children's ward, which is the gift of **Dr. and Mrs. Charles P. Bancroft**, in memory of a deceased infant son.

St. Rose's Home for Cancer and the **Molly Fancher Memorial for Cripples** have each received \$1,000 by the will of **Florence Starr**.

Medical Society Elections.—THE FORREST COUNTY (MISS.) MEDICAL SOCIETY, at its meeting in Hattiesburg, Miss., on February 9, elected the following officers: *President*, **Dr. Leo H. Martin** of Hattiesburg; *Vice-President*, **Dr. J. J. Bethea** of Hattiesburg; *Secretary-Treasurer*, **Dr. May F. Jones** of Hattiesburg.

THE CABBARUS COUNTY (N. H.) MEDICAL SOCIETY, at its meeting in Concord, N. H., on February 8, elected the following officers: *President*, **Dr. S. W. Rankin**; *Vice-President*, **Dr. W. E. Pemberton**; *Secretary-Treasurer*, **Dr. J. A. Patterson**, all of Concord, N. H.

Free Clinical Instruction in Contagious Diseases.—The second course of instruction in contagious diseases, conducted at the Kingston Avenue Hospital, Brooklyn, under the direction of the New York City Department of Health, will begin on March 5, at 3 P. M. The course will last two weeks, and will consist of eight lessons, six devoted to clinical bedside instruction, one to a demonstration of intubation, and one to practical laboratory work. The clinical instruction is given under the direction of **Drs. Ager, Spingarn, and Ratnoff**. Laboratory instruction is given under the direction of **Dr. William H. Park**. No fees are charged.

All Horses to Be Tested for Glanders Infection.—The Board of Health, in order to deal more efficiently with the problem of eradicating glanders infection among the horses in New York City, has added the following section to the Sanitary Code: "No horse shall be brought into or kept in the city of New York unless it shall have been tested and found to be free from glanders by a duly licensed veterinarian, in accordance with the regulations of the Board of Health."

Obituary Notes.—The Rev. **Dr. GEORGE S. BAKER**, for twenty-three years pastor and superintendent of St. Luke's Hospital, New York, died last week at his home in this city. He was born in Medford, Mass., in 1838, and was appointed superintendent at St. Luke's, succeeding the founder of the hospital, **Dr. Muhlenberg**, in 1877.

Dr. ANTRANIG AYVAZIAN of New York city died of lobar pneumonia in the Polyclinic Hospital, on February 15, aged 67 years. He was graduated from New York University, medical department, in 1886, and was for many years a medical inspector with the Board of Health.

Dr. R. L. PAYNE, SR., of Norfolk, Va., died suddenly of heart disease at Durham, N. C., on February 8, aged 61 years. He was graduated from Jefferson Medical College, Philadelphia, in 1881, was a Fellow of the American College of Surgeons, president of the medical staff of St. Vincent's Hospital, chief surgeon of the Norfolk Southern Railway and the Chesapeake and Clyde Steamship companies, medical director of the Jamestown Exposition, and ex-president of the Norfolk Medical Society.

Dr. BENJAMIN R. SWAN, of San Francisco, died at the Adler Sanitarium of pneumonia, on January 27, aged 81 years. **Dr. Swan** was a graduate from the College of Physicians and Surgeons, New York, in 1868. He was a Civil War veteran, Coroner of San Francisco for a term, and in 1875 became professor in the medical department of the University of California, where he taught until his resignation in 1890.

Dr. STEPHEN W. GERARD, a retired physician of St. Joseph, Mo., died at a hospital in that city, on January 31, aged 84 years.

Dr. GEORGE B. LAWRASON of Shreveport, La., died at the Touro Infirmary, on February 3, aged 63 years. He was graduated from the Medical Department of Tulane University in 1883. He was an army surgeon in the Spanish-American War, and later served in the Philippines, where he had the rank of major conferred upon him.

Dr. JAMES WILLIAMSON, a graduate of Vanderbilt University Medical Department, Nashville,

Tenn., in 1905, died of tuberculosis on February 4, aged 38 years.

Dr. WILLIAM NELSON MEBANE died of pneumonia at his home in Hillsboro, N. C., on February 5, aged 38 years. He was graduated from the George Washington University, Washington, D. C., in 1906.

Dr. H. A. SMITH of Waterville, Wash., a graduate of Lincoln Memorial University Medical Department, Knoxville, Tenn., in 1892, died on February 2, aged 50 years. He formerly resided in Knoxville, Tenn.

Dr. ALBERTUS JOSEPH, a graduate of the State University of Iowa Medical Department, in 1900, and for many years connected with that institution as an instructor in surgery, died at his home in Iowa City on February 4, aged 48 years.

Dr. CHARLES DEXTER SAWIN, a graduate of Harvard Medical School, in 1882, died suddenly at his home in Somerville, Mass., on February 8, aged 65 years.

Dr. EDWARD A. HENNESSEE of Morgantown, N. C., a graduate of the Chattanooga Medical College, in 1900, died suddenly on January 29, aged 45 years.

Dr. M. S. SILVA, a graduate of the California Medical College, in 1901, died at his home in Sacramento on January 20, aged 55 years.

Dr. EDWARD P. ANSHUTZ, retired from active practice, died at his home in Philadelphia on January 31, aged 46 years. At the time of his death he was editor of the *Medical Recorder* and the *Homeopathic Envoy*.

Dr. EDWARD B. HAMPTON of Elkin, N. C., a practitioner of medicine for nearly seventy years, died on February 1, at the age of 93 years.

Dr. ELI PERCIVAL FLINT, a graduate of Yale University Medical Department, in 1879, died of pneumonia at his home in Rockville, Conn., on January 31, aged 69 years.

Dr. EUGENE CHASE PECK of South Boston, a graduate of the University of Vermont College of Medicine, in 1869, died at the Massachusetts Homeopathic Hospital, February 3, aged 77 years.

Dr. GEORGE F. RODIER, a graduate of Laval University Medical Department, in 1899, died of Bright's disease at his home in Natick, R. I., January 27, aged 48 years.

Dr. FRANK E. WHITNEY, a graduate of New York University Medical School, in 1881, died of uremia at his home in Rochester, N. H., on January 24, aged 65 years.

Dr. EDWARD DYER ELLIS, a graduate of Harvard University Medical School, in 1877, died of heart disease at his home in Poultney, Vt., on January 24, aged 68 years.

Dr. ALFRED L. S. MORAND, a former acting assistant surgeon of the United States Army, and for many years a practising physician of South Boston, Mass., died at his home in that city on January 30, aged 80 years.

Dr. CARROLL G. ZERRETT of Norfolk, Va., died suddenly in that city on February 7, at the age of 50 years. Dr. Zerrett formerly practised medicine in Boston.

Dr. JULIAN H. EVANS, a graduate of Vanderbilt University Medical Department in 1887, died following an attack of acute indigestion at his home in Sandersville, Ga., on January 23, aged 51 years.

Dr. M. S. SILVA, a graduate of the California

Medical College, San Francisco, in 1901, died at his home in Sacramento, Cal., on January 20.

Dr. ELISHA B. MOORE, a graduate of the University of Nashville Medical Department in 1868, died at his home near Ripley, Ala., on January 17, aged 82 years.

Dr. O. A. ODELL of Hall's Cross Roads, Tenn., a practising physician for sixty-four years, died after a brief illness, on January 20, aged 83 years.

Dr. O. BEN STROUD of Ore Hill, N. C., died after a brief illness in a local hospital, at the age of 68 years.

Dr. JECHIEL TCHLENOV, a leading physician of Moscow, Russia, died on February 3, at the age of 58 years. He gave up a lucrative medical practice in order to devote his time to the Zionist movement.

Dr. CHARLES C. HAWKINS, a graduate of the medical department of Tulane University in 1876, died after a long illness at his home in Waco, Tex., on January 24, aged 62 years.

Dr. IVAN E. BELLINGER of Sweet Home, Ore., died of pneumonia at Fort Riley, Kan., on January 17. Dr. Bellinger was a graduate of Willamette University Medical Department in 1913 and a lieutenant in the Medical Reserve Corps.

Dr. GEORGE H. LATHROP, a graduate of Bellevue Hospital Medical College in 1875, died at his home in Livingston Manor, N. Y., on February 15, aged 68 years.

Dr. JOHN A. O'BRIEN of New York City, a graduate of the Galveston, Tex., Medical College in 1875, died at his home on February 18.

Dr. HORATIO F. COPELAND, a graduate of Harvard Medical College, in 1865, died, following a stroke of apoplexy, at his home in Whitman, Mass., on February 8, aged 76 years.

Dr. ROBERT F. STRATTON died of heart disease at his home in St. Joseph, Mich., on February 7. He was graduated from the Harvard Medical School in 1853, and served as an army surgeon during the Civil War, with the rank of major. He was for many years a pension examiner.

Dr. D. B. MORROW, a graduate of the Pulte Homeopathic Medical College, Ohio, and an ex-president of the Homeopathic State Medical Society, died at his home in Dallas, Tex., on February 8, aged 79 years.

Dr. HARRY MADISON CUTTS of Brookline, Mass., died on February 22, aged 60 years. He was a graduate of Harvard Medical School in 1883, medical examiner of Norfolk County, Mass., for more than twenty years, and for many years superintendent of the Garfield Memorial Hospital Washington, D. C.

Dr. A. G. HAGADORN, a graduate of the University of Michigan, in 1871, and a practising physician of Lansing, Mich., died at his winter home in St. Cloud, Fla., on February 11, aged 75 years.

Dr. ALEXANDER CAMERON BROWN, a graduate of the Hospital College of Medicine of the Central University of Louisville, Ky., died of pneumonia, at his home in Lexington, Ky., on February 6, aged 30 years.

Dr. TALIOS K. SERIJANIAN, a graduate of the College of Physicians and Surgeons, Boston, in 1890, died in Lawrence, Mass., on February 7, aged 53 years. He was a resident of Worcester, Mass., for a number of years before removing to Lawrence.

Dr. CHARLES M. FRISSELL of Wheeling, W. Va., a graduate of the College of Physicians and Surgeons, New York, in 1882, and founder of the Hospital Training School for Nurses in Wheeling, W. Va., died on February 12, aged 58 years.

Dr. OSCAR G. McMULLAN of Elizabeth City, Va., a graduate of the Medical Department of the University of Virginia, in 1880, died of pneumonia on February 13, aged 61 years.

Dr. AMBROSE J. GALLISON, a graduate of the Medical Department of Dartmouth College, in 1837, died of angina pectoris at his home in Franklin, Mass., on February 13, aged 62 years.

Dr. ALBERT HOMER BURKET, for forty-three years a practitioner of medicine, died at his home in McKees Rocks on February 12, aged 71 years.

Dr. CHARLES R. GOUGH, a graduate of the Marquette University, Milwaukee, died at his home in Wausau, Wis., on February 12, aged 31 years.

Correspondence.

MEDICAL RESERVE STATISTICS OF NEW YORK STATE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Believing it will be of interest to all the physicians of New York, I am enclosing a schedule of the various counties of New York State, arranged on a basis of the percentage of their total physicians already recommended for commission in the Medical Reserve Corps. It should be noted that two counties, Hamilton and Putnam, are so situated as regards the geographic distribution of their medical and general population that actually no physicians can be spared. All are needed by the local communities. The fact that they have furnished no applicant for commission must not therefore be counted against them. On the other hand, large population centers like Brooklyn, Buffalo, Rochester, Syracuse, and Utica have, in general, an excess of medical talent and might properly have been ex-

pected to furnish a percentage nearer to that of Albany, New York, and Troy.

F. T. VAN BEUREN, JR., M.D.
Executive Secretary, Council of National Defense, New York State Committee, Medical Section.

Progress of Medical Science.

 4. Gastroduodenal Perforation: A New Diagnostic Sign. Martin T. Field.
 5. Severance of the Chorda Tympani Nerve. Irving Sobotky.
4. Gastroduodenal Perforation: A New Diagnostic Sign.—Martin T. Field says that the diagnosis of perforation of the stomach and duodenum must many times remain in doubt unless aided by some distinctive and reliable sign, independent of parietal peritoneal irritation and tension. In every case of perforation, gas and fluid are present in varying amounts in the free peritoneal cavity. The gas may pass between the liver and diaphragm, as shown by the x-ray, and cause obliteration of liver dullness. Much dependence cannot be placed on liver percussion as ordinarily practised, because of the very great variations, both in health and disease. Change of patient's position will cause the fluid to flow to the dependent part, and the air to rise to the top. *This will intensify the findings; tympany over a wide liver area and again flatness over the same area on change of position.* Normally there is a change in the liver percussion note on change of posture. This was noted in a large number of normal cases examined, but in none of these were the results similar to those found in the cases reported. Normal liver changes must be recognized before positive deductions are made. A fair comparison is the difference detected in shifting flank dullness in moderate ascites and in the normal abdomen. The writer believes that this sign is of considerable value, and should be sought for in every case. If absent, in the presence of other positive signs of perforation, it may be disregarded, but if present in doubtful cases, it may be the deciding diagnostic factor.

2. The Cure of Heart Disease in America as Replacing the Heart Cures in Europe.—Louis Faugères Bishop defines and describes the course of treatment for diseases of the heart as formerly conducted at special European resorts and then considers what there is in this country to take its place. The benefit received was not only from the baths but depended largely upon other factors, such as the dropping of business cares, the enforced rest to body and mind during the voyage, the distraction of a week or two in London and Paris, the growth of faith inspired by the belief of the "Kur" doctor in the efficacy of his treatment, and finally the quiet aftertreatment in Switzerland or elsewhere. An essential feature is change of environment which can be obtained here by going to some other city—the New York business man, for example, should seek the restful atmosphere of Philadelphia. The patient should agree to give up five or six weeks to the course of treatment, but even then it is difficult to imitate the spirit of re-

laxation which pervaded the European resort and to get the mental uplift that comes from a crowd of people all taking the treatment in a hopeful spirit. There is need in this country of some resort that will be specially for heart patients, including those with high blood pressure conditions. Many resorts have started in this direction, but each time they have been dissatisfied with the limitation of their work and have spread out to cover every known ailment and have consequently failed in the proper development of their heart cure. For those who cannot leave home, a careful physician can substitute a fairly good cure, provided he has sufficient control of the sufferer. He can gain the consent of his patient to a course of treatment covering three to six weeks. He can make his thorough examination with the x-ray, the electrocardiograph, the polygraph, and the sphygmomanometer. He can have a Wassermann reaction, a urinalysis, a blood count, and such other observations as his condition suggests, as well as is done in a foreign cure resort. He can reduce his drugs to the actual need of the person. He can institute hydrotherapeutics, graduated exercises, and other measures as may be needed. He can perhaps persuade his patient to give up some of his worrisome business affairs and then send him to some quiet and distant place for an aftercure. But, after all, what is really more needed for the cure of heart disease in America as replacing the heart cures of Europe, is a keen realization of the problem rather than the discovery of a particular resort.

1. An Experimental Investigation of Lipovaccines: a Preliminary Note.—E. R. Whitmore, E. A. Fennel and W. F. Petersen refer to the advances made in both medicine and surgery since the advent of the war, especially do they call attention to the preparation of vaccines, of which lipovaccines are a brilliant example. Their investigations have been carried out from the Department of Pathology, Army Medical School, and they have found that among the advantages derived from the use of oil vaccines may be considered: (a) the diminution of both the local and the systemic reaction; (b) the feasibility of giving sufficient vaccine at a single injection properly to immunize the individual; (c) the persistence in the individual of a focus from which the immunization proceeds over a period of several months with a resulting lengthening of the period of immunity; (d) the actual detoxicating effects of certain lipoids that can be incorporated in the vaccine, and (e) the prevention of autolysis and deterioration of the vaccine. The vaccine used in the Army for prophylaxis against typhoid and paratyphoid fevers contains 1,000 million typhoid and 750 million each of paratyphoid A and B per cubic centimeter, given in three doses, the first of 0.5 c.c., the second and third of 1 c.c. each, the total number of organisms used being, therefore, 6,250 million. This method of immunization, as introduced by Colonel Russell, gives practically complete protection for a period of several years. When a dose of 7,500 million organisms is prepared as a lipovaccine, either in olive oil or oil of sweet almonds, it can be given with less local reaction than that which follows a single dose of the aqueous vaccine, and an almost entire absence of constitutional effects. The possibility of giving the entire immunizing dose at one time is, for military purposes, an advantage in relieving the medical service from a not inconsiderable routine of injections and record work as well. With a lipovaccine, absorbing over a long period of time, the immunity might be conceivably prolonged. Lipovaccines make it possible to take

advantage of the distant detoxicating effects of certain lipid combinations, and in this way lessen the reaction, quite apart from the delayed absorption. Also from a technical point of view the autolysis of the organisms is largely prevented and the deterioration of the vaccine reduced. They have prepared a series of vaccines including (a) typhoid-paratyphoid (A and B); (b) pneumococcus (types I, II and III); (c) meningococcus (types 1, 10, 30 and 60); (d) dysentery (Shiga, Flexner and Y). They state that the choice of oils used in the preparation is rather limited. The mineral oils were first tried by the French, but were discarded in favor of the vegetable oils, such as olive, sweet almond and poppy. The oils must be nonirritating, of slow absorbability, must not be too viscid for injection, should withstand complete sterilization with alteration, and must be available in the market in reasonable quantities. They consider that while they regard their work as purely preliminary, they have gained the impression that the lipovaccine offers a number of advantages over the aqueous preparation. The production of the vaccine is, of course, more laborious and expensive, and a number of technical problems remain to be studied in connection with it, together with detailed investigations of the comparative antigenic value. Apart from the typhoid-paratyphoid A and B preparation, the pneumococcus and meningococcus vaccines have been of interest to us because of the apparently ready response in agglutinins of both animals and man to a single injection. Whether such a response properly portrays the protective value of the vaccine is, of course, not to be determined in so short a period of time as has been available to us. Protection tests in animals vaccinated with the triple typhoid lipovaccine have indicated the development of a considerable degree of resistance, and similar experiments carried out in mice following pneumococcus vaccination gave some evidence of protection. The latter experiments, together with those under way with meningococcus vaccine, are, however, not sufficiently advanced to permit them to draw definite conclusions.

The Lancet.

February 2, 1918.

1. Two Addresses on War Psychoneurosis. (II) The Psychology of Soldiers' Dreams. F. W. Mott.
2. An Address on the Repression of War Experience. W. H. R. Rivers.
3. The Predisposing Factors of War Psychoneuroses. Julian M. Wolfsohn.
4. Observations Upon Prognosis, with Special Reference to the Condition Described as the "Irritable Heart of Soldiers." Thomas Lewis.

3. The Predisposing Factors of War Psychoneuroses.—Julian M. Wolfsohn finds that throughout the massive literature which has sprung up within the past three years one reads passing references mostly to the relation of the symptoms of war psychoneuroses to a previous neuro-potentially unsound soldier; most authors have elicited an inherited or acquired neuropathy in the majority of their patients afflicted with shell shock, neurasthenia, or any of the neuroses resulting from the strain of the war. But enough actual specific data on the inherited and acquired neurotic factors in these cases have not been published. Before drawing generalizations on this subject, one should try to answer some of the following pertinent questions: (1) Of what kind of forbears is the patient a representative? (2) What is the personal temperament of the patient? (3) What was his former calling, and how has he shouldered his responsibilities during active war service? (4) Do acquired war psychoneuroses occur, and what are the causes thereof? (5) What is the relation of the last "shock" to the production of the war neurosis? (6) Why do not all soldiers suffer from war neurosis? Before answering any of these questions one must examine all available data, up to the time of active service, and also the actual causes and circumstances exciting the outbreak of the neurosis, realizing that every individual's nervous system will react according to his inherited tendencies superimposed on the effects produced by environment. Therefore the object of this special work is to make an intensive study of the casual factors of war neurosis as presented by the family and the personal histories (up to the time of, and including the cause of, disablement) of 100 cases of war psycho-

neurosis—viz., shell shock, neurasthenia, hysteria, and exhaustion. Insane cases are not included in this paper. As a control 100 cases of somatic injuries produced in the firing-line—viz., enucleation of an eye, fracture of the skull, jaw, femur, amputations, and wounds, with or without sepsis, have been similarly studied. The exhaustive history in most of the cases was given by the patient himself. In some cases the help of the wife or mother was necessitated to get as much first-hand available data as possible. From this study of 100 cases of war psychoneuroses and 100 cases of somatic injuries produced in the firing line Wolfsohn finds he can draw the following conclusions: Cases of war neurosis are very rarely associated with external or somatic wounds. The vast majority of the psychoneurotic cases studied were among soldiers who had a neuropathic or psychopathic soil. In 14 per cent. of these cases a family history of neurotic or psychotic stigmata, including insanity, epilepsy, alcoholism and nervousness, was obtained, whilst a previous neuropathic constitution in the patient himself was present in 72 per cent. A gradual psychic shock from long-continued fear, together with the sudden change from quiet peaceful environment to the extraordinary stress and strain of trench fighting, is the chief predisposing cause of war psychoneurosis in soldiers with neuropathic predisposition. In fact, these factors may be the cause of the neurosis *per se*. The history of the individual previous to enlistment has an influence on the character and gravity of the symptoms of the neurosis. Acquired neuroses with their less severe symptoms appeared only after excessive fatigue, with the concussion from the high-explosive detonation acting as the exciting factor. On the other hand, in the same abnormal environment, and with the same powerful factors obtaining, wounded soldiers do not suffer from war neuroses except in rare instances. In the wounded soldiers studied no neuropathic or psychopathic stigmata occurred in the family history. Previous neuropathic tendencies were found in 10 per cent. of these patients (controls), all of which number presented mild neurasthenic symptoms. Hysteric manifestations, such as monoplegia in a wounded limb, are occasionally encountered in injured soldiers.

 6. The Treatment of Amebic Dysentery with Emetine and Bismuth Iodine. A. C. Lambert.
5. A Survey of 1,064 Operations for the Complete Removal of Tonsils and Adenoids.—Edward D. D. Davis states that the consideration of the large number of operations performed for the removal of the faucial tonsils and adenoid growth, or hypertrophied pharyngeal tonsil, makes one pause to wonder whether all these operations are really necessary. It must be remembered that the tonsils, both faucial and pharyngeal, are normal structures present for some definite purpose in every child. When the tonsils and adenoid growths are septic, diseased, or hypertrophied, so that their presence produces definite and harmful symptoms, every one will agree that they should be efficiently removed, but the predisposing and exciting causes of infection and enlargement of these structures should be reviewed before deciding that operation is necessary. The experience gained by a close study of 1,064 cases, in addition to those seen during seven years in charge of a London County Council school clinic for affections of the nose, throat and ear, may throw some light on their etiology. The cases have been carefully examined before operation, they have been seen two or three hours after operation, again one week afterwards, and, finally, six months later. The strumous or scrofulous child, the child living in poor, dirty surroundings, present so often cases of enlarged tonsils and adenoids. Operations are usually successful when the hygienic surroundings admit of clean living. Otherwise failure in operation is courted. The results of operations in the carefully selected and well-marked cases are excellent; not only

are the symptoms relieved, but there is a great improvement in the general health and comfort, due to the fact that the child sleeps better, its appetite is increased, the hearing improves, the frequent and prolonged colds cease, the flat chest develops, and growth is more rapid. The removal of adenoids in the so-called idiopathic asthma of the nervous, wheezy child has no beneficial effect, and most of these children have no adenoid growth. Idiopathic asthma must not be confused with the intermittent suffocative attacks during sleep, which are due to adenoids, and are cured by the removal of the growth. A large number of children have attacks of earache and deafness during colds, with retraction of the drums, which frequently suppurate; and if such a case is allowed to continue without operation, the deafness or dulness of hearing becomes permanent, and is beyond cure. The affection of the ears makes operation imperative. In all cases of earache and deafness operated on the ears become normal, except in the older patients, in whom the damage has been done by the long duration of the inflammation. Cases of recent suppuration rapidly heal and the otorrhea ceases. The mouth breathing and frequent colds disappear if the patient is made to perform suitable exercises to expand the chest and to promote nasal breathing. No operation is complete unless followed by a course of breathing exercises and the teaching of children to blow their noses efficiently every morning. The parents are told that breathing exercises are as important as the operation, and should be carried out every day for at least six months, commencing a fortnight after operation. Occasionally a school child will have a temperature, of obscure origin, of 100° with a rise to 102° or more for some weeks following a so-called influenzal cold which on careful inquiry is seen to have been tonsillitis. There is slight tonsillitis with enlargement of the cervical tonsil lymphatic glands. The enucleation of the tonsils cures the fever, and the cervical glands slowly disappear. There are two types of enlargement of the upper deep cervical set of glands as the result of infection of the tonsils. The first is inflammatory, and accompanies most attacks of acute tonsillitis, and disappears with the tonsillitis. In repeated attacks of tonsillitis the enlargement, which is limited to the tonsil gland of the upper deep cervical group, becomes chronic, but gradually disappears after the removal of the tonsils. The second type of enlargement is tuberculous, is more marked, and there is extension to the other glands of the deep cervical group. If the case is early and the glands are not caseating, removal of the tonsils with suitable antituberculous treatment results in their disappearance, but the majority of hospital cases require removal of the glands in addition to the tonsils. Nocturnal enuresis has been stated to be due to adenoid growth and its accompanying suffocative attacks during sleep, but in Davis' experience true regular enuresis occurring every night is rarely, if ever, due to adenoids. Very few children with well-marked adenoid growth have this symptom, and he has seen a number of cases of enuresis with absolutely no adenoid growth. Moreover, the removal of the adenoids has not cured the enuresis. Whatever the function of the tonsil may be its structure and behavior are similar to that of a lymphatic gland, and it is reasonable to suppose that the remaining lymphatic tissue of the pharyngeal wall, the lingual tonsil, and cervical glands compensate and take on the function of the tonsils and tissue removed, but he has not seen hypertrophy of any of these structures after operation, not even the cervical glands. He has carefully examined a large number of children six months or more after operation, and has endeavored to follow up cases, and has not observed any deleterious effects or disadvantages following removal of tonsils and adenoids. He has not obtained any evidence to indicate that the removal of the tonsils predisposes these children to diphtheria, scarlet fever, or other acute infections, but has seen several cases of unhealthy spongy tonsils yielding cultures of the Klebs-Loeffler bacillus weeks after the quarantine period had elapsed. E. W. Goodall and J. D. Rolleston both state that in their experience there is no reason to think that children who have had tonsils and adenoids removed are more susceptible to scarlet fever or diphtheria. He has not seen and has no records of tuberculosis of the cervical lymphatic

glands appearing after removal of the tonsils. In conclusion, when a child has a specific set of injurious symptoms which can be definitely attributed to the tonsils and adenoid growth, nothing but benefit results from removal, but there is a need for careful examination and selection of operation cases. An attempt should be made to ascertain and eliminate the cause of the condition under observation before the question of operation is finally settled.

Tuberculosis (Continued from previous issue).—E. Schloss develops the study of an epidemic of tuberculosis undertaken by him in an orphan asylum. He puts forward general considerations on the technique, the diagnostic and prognostic value of the cuti-reaction and that of tuberculine. His conclusions are somewhat guarded. Given the ignorance in which we now stand as far as the real genesis of the symptoms is concerned, it would be premature to assign to them a precise signification. The success in the way of cures from tuberculin, which result in the disappearance of the reaction, keeps one from looking upon it as an indication of organic defense. Cuti-reaction is rather more an indication of the defensive combat itself than of an organic capacity for the combat, since it may disappear when in the presence of clinical precision. Finally, Schloss does not even admit the current opinion that infantile tuberculosis is a sort of vaccination for adult life, because were it so the class of people in easy circumstances which is relatively free from infantile scrofulosis should furnish a greater contingent of tuberculosis in the adult, which is far from being the case.

The Present State of Our Knowledge in Respect to War and Traumatic Neuroses.—H. Oppenheim, in a long polemic, which is especially addressed to Naegeli, the rejector of the theory of traumatic neuroses, brings up to date his former opinions which he has rectified from the data collected from the present war. "The functional nervous disturbances resulting from emotion are more commonly transitory in nature; they may become fixed from desire, of claiming tort, and therefore results a resistance to cure. But inversely their duration should not allow one to attribute them to this mechanism." A great progress, the result of war experience, resides in the fact that suggestion and comminatory (Zwangsbehandlung) treatment bring about a rapid disappearance of the symptoms most evident. However, in the majority of cases this result does not correspond to a real cure and leaves the subject much inclined to relapses. The degree of incapacity for work is less considerable in commotional neuroses than Oppenheim and others had formerly supposed. Pensions and indemnities are, therefore, not to be allotted in: (1) Slight cases; (2) in "pension neurosis" (Reutenkampf-neurose) and (3) when there is reason to suppose that an obligation to work may result in recovery.

December 4, 1917.

Treatment of Wound Erysipelas by Silver Nitrate.—Gaugele refers to a former article of his (*Deutsche medizinische Wochenschrift*, No. 15, 1917) and again insists on his treatment because of its continued encouraging results. The writer's procedure is as follows: At the distance of about a hand's breadth from the red area he marks with a silver nitrate stick a circular line around the limb involved. The stick is first moistened and is then applied with considerable pressure on the surface so as to provoke vesiculation. Next, the entire distal segment of the limb is coated with a 20 per cent. solution of silver nitrate. A cure of the erysipelas is produced in twenty-four hours. The writer does not hesitate to look upon his treatment as the specific one of traumatic erysipelas.

Weil's Disease and the Point of Entrance of Its Pathogenic Agent.—J. W. Miller has been the first to describe the changes taking place in the tonsils in this disease. These consist in a hyperemia, often even a hemorrhagic injection, and above all the presence of

small miliary vesicles in the domain of the epithelium of the crypts. The writer regards these vesicles as specific of Weil's disease. This general aspect of the tonsil may be effaced by superadded infections. The histologic picture of the cervical lymph nodes is characterized by: (1) A catarrhal process of their sinuses, and (2) an inflammatory hyperemia with capillary thromboses. Miller believes that the point of entrance of the icterogenous spirochete is in the rhinopharynx, this organism being the specific agent of the affection under consideration. Clinical studies corroborate this view from the fact that there is dysphagia resulting from an angina, redness and edema of the pharynx and uvula. Contagion takes place, as in the plague, by the intermediary of rats, whose urine and feces contain the specific organism of the disease. Finally, the writer relates this disease to scarlet fever, inasmuch as it is similar from the development in both processes of exanthemata, nephritis, otitis, etc. On the other hand, there is no relationship between Weil's disease and acute yellow atrophy of the liver.

Deutsche medizinische Wochenschrift.

December 6, 1917.

Typhoid Carriers and Widal's Reaction.—Hilgermann has endeavored to discover the bacillus of Eberth in the stools of subjects suspected of carrying the bacilli by means of agglutination. By thus replacing the tedious and deceiving procedure by a more exact research and one less liable to be rendered inexact by the subject himself a surer conclusion can be arrived at. By using a broth inoculated with bacilli of various origins the writer comes to the conclusion that a positive Widal always indicates the presence of a typhoid focus in the body. There are no typhoid carriers who do not give a positive Widal. In convalescents from typhoid, agglutination is positive only for four or five months, and if it continues beyond this time it implies, contrary to the general opinion, that the subject is still in a latent typhoid state. Very happily, the writer considers a negative Widal as proof of the absence of typhoid bacilli in the body. He is about to prepare a further publication in proof of his views.

Restrictions to Be Formulated in the Treatment of Serious Cases of Enteritis with Bolus Alba.—J. Bunge records the history of a patient presenting hysteria in which the exhibition of bolus alba resulted in intestinal occlusion which necessitated surgical interference and resulted in the patient's death. The writer comes to the conclusion, after offering a discussion on other possibilities which may arise from this treatment that it is not without danger, and he further bears out this conclusion by reporting two cases in which bolus alba, exhibited at the dose of 200 grammes in water, produced a marked paresis in intestinal evacuations. Bunge recommends particular prudence in cases where there is a history of former intestinal trouble, likewise in enteroptoses and chronic constipation.

The Bacteriology of Dysentery.—U. Friedmann considers epidemic hemorrhagic colitis as being exclusively caused by well-known bacilli. He has not been able to observe any appreciable results to be derived from anti-dysenteric serum.

Wiener medizinische Wochenschrift.

December 8, 1917.

Extragenital Syphilitic Infections in Wartime.—A. Seidl relates in a summary way the histories of twenty-five cases of syphilis contracted otherwise than by coitus. The frequency of these infections as compared by their former frequency as offered by the statistics of Vienna (78 cases from 1889 to 1908) shows that for the period of January, 1915, to February, 1917, there has been a considerable increase of lues in general. The primary localization of the extragenital infection has been 2 cases of digital chancre, 10 chancres on the lips, 10 on the tonsils, one on the tongue and one on the upper lid. Generally speaking, the evolution of the disease offers nothing in particular other than the abnormal site of the initial sclerosis. The writer has not met with any cases of extragenital ulcers mollor in spite of their frequency, particularly at the com-

mencement of the war. This frequency, however, was only temporary and later on hard chancres predominated, while there was a period during which mixed chancres were particularly prevalent.

Multiple Fractures of the Skull from Shrapnel; Gangrenous Encephalitis; Excision of Brain Tissue; Drainage; Recovery.—R. Kropac has operated with success on a wounded man who appeared to offer a minimum of chance for a favorable result. The wound, resulting from an exploding shell, was located on the right side of the head. The writer attributes the successful outcome of his operation, which left the patient with the use of his limbs and an intact mental condition, to free drainage and above all to a musculocutaneous plastic operation covering the exposed cerebral mass. The advantages of this latter are evident, as it protects it against the air and results in a permanent moistening of the wound and stimulation of its secretions.

Hygeia.

December 30, 1917.

Albuminuria in Icterus.—Höjer seeks to demolish the old view that the albuminuria of icterus is due to the cholemia, the retention within the blood of certain bile constituents. He would explain it by the theory that the toxic substances present in the blood in icterus damage the parenchyma of both liver and kidneys and hence set up both jaundice and albuminuria.

Irrigation of the Ear with Alternating Heat.—Alfelt recommends that 100 c.cm. of warm water (42°-43°C.) be first thrown into the ear and followed at once by 5 to 10 c.cm. of cold water of ordinary hydrant temperature. This sequence is to be maintained until one liter of warm water has been used. The last injection should be warm. The ear should then be carefully dried and a cotton pledget worn for one hour. There should be a daily session for a period of 4 to 6 weeks, although good results may follow a less assiduous course. The author has treated by this means adhesive catarrhs, otosclerosis, nervous deafness without known cause, deafness from loud noises and from arteriosclerosis. In most cases the hearing improves, although at times tinnitus, etc., persists.

Correspondenz-Blatt für Schweizer Aerzte.

December 22, 1917.

Progress in Our Knowledge of Defensive Ferments.—Abderhalden writes briefly upon the advance of our knowledge of the reaction which goes by his name. This comprises the conception of "zelleigen" and "zellfremd" substances as something over and beyond "arteigen" and "artfremd" matter. Still another conception is "bluteigen" and "blutfremd." If a person's muscle is injured, for example, the blood shows later the presence of a ferment which can disintegrate muscle albumin. Every "zelleigen" substance is "blutfremd" or foreign to the blood. The thyroid tissue in a given subject is foreign to the liver cells of the latter. These distinctions have been elaborated by Hamburger through series of experiments. Much activity has been shown in the province of the demonstration of defensive ferments by various methods, as polarization, dialysis (both long used), precipitation, charging with coloring matters and metals, use of the interferometer and refractometer. A micro method has been introduced in which a few drops of serum may serve for analysis.

Prolonged Use of Camphor in Chronic Myocarditis.—Zangger sought ten years ago for a remedy for this affection which could be administered month in and out without prejudice. Incidentally camphor tincture was tested, 10 or 15 drops t. i. d., because of its known stimulant action on the heart muscle and its vasodilator activities in the peripheric circulation. The first person to be tested thus was a woman aged 76 with many petty symptoms of cardiac insufficiency due to stasis. After 4 months of treatment the woman was able to leave the bed and attend early Mass. She was kept going by camphor for 4 years, dying after anginal attacks and beginning senile dementia. Since then Zangger has treated nearly 100 cases of chronic myocarditis in subjects over 65 years of age, including those in the eighties and nineties. Camphor was used con-

tinuously and in acute crises digitalis or pituitrine-adrenaline. The author must therefore take issue with Mackenzie when the latter states that camphor is without action on the heart.

Sterility and Retroflexio Uteri.—Herzog sums up the causes of sterility as follows: Male insufficiency, 33 1/3 per cent.; female gonorrhea, 33 1/3 per cent. The remainder comprise a host of petty factors, among which is retroflexion. The profession are very skeptical concerning the cure of sterility through correction of this deformity, but there is plenty of evidence that this result is attainable. For example, Bamm has seen conception frequently follow shortening of the round ligaments in retroflexion cases. A distinction must be made between the virginal type, in which defective development is at fault, and the secondary form. In the former, with the uterus nearly doubled on itself, the wearing of a pessary was followed by conception. Pessaries, however, are burdensome to nulliparæ. The author claims to have cured a primary case by means of an Alexander-Adams operation and also two secondary cases by the same resource and by a Gilliams ventrofixation respectively.

La Riforma Medica.

January 19, 1918.

Two Cases of Suppurative Paraneuphritis of Tonsillar Origin.—Botteselle refers to the occurrence of paraneuphritic phlegmon as a metastasis from local infections of all kinds and from infected blood states. This lesion has received numerous designations and its precise seat and pathogenesis have been much debated. The fibrous capsule of the kidney, the connective tissue which invests it and the perirenal fatty tissue may doubtless be attacked individually and separately, but the incidence of the affection is largely due to the presence of the adipose tissue which is in close relationship with the renal capsule. It is not apparent why in a hematogenous infection this tissue should invite metastasis, and the prevalent view is that various microorganisms on their way toward elimination by the kidneys migrate from the latter into the pararenal tissue, an activity which is greatly facilitated by the arrangement of the blood vessels. Both patients were young women who complained first of distress in the right flank, with a systemic reaction which caused them to take to their beds. The antecedent tonsillitis was mild and in one case must have been very pugnacious. This patient seems to have had a purulent infection of a finger, as shown by a recent scar; this was perhaps itself a metastasis—or it may have been the original source of infection. The symptoms in the flank showed aggravation and the general reaction suggested some septic qualities. Everything pointed to suppuration in the region of the right kidney. In one patient the urine was quite normal, while the other showed the presence of albumin, red cells and casts. On employing the segregation it was found that the function of both kidneys was disturbed, while both showed minimal evidences of infection. In both subjects, however, the urine was sterile, or at least negative to culture tests. The author, despite the finds in one case, regards the kidneys as practically intact. In both cases the blood examination showed some leucocytosis. Sudanophiles were present, but not in a marked degree. Blood cultures are not quoted. In but one patient was an x-ray taken, showing a faint shadow under the liver. Both patients were treated by incision over the suppurating area, which evacuated a certain amount of pus. The cause in one case was the streptococcus; in the other the staphylococcus, which were isolated from the latter. In such cases we are justified in concluding that it is the business of the kidneys to eliminate pathogenic bacteria which have found entrance into the blood. At times the kidneys themselves become involved, at others the bacteria migrate through the capsule into the perirenal tissues. There are also cases of the ascending type in which pyelonephritis develops as a sequel of cystitis. Here, too, there may be a migration of bacteria through the walls of the urinary tract. Finally, the author says, bacteria likewise very often progress through the intestinal wall into the perirenal tissues.

Book Reviews.

MEDICAL WAR MANUAL No. 2 (Authorized by the Secretary of War and under the Supervision of the Surgeon-General and the Council of National Defense). NOTES FOR ARMY MEDICAL OFFICERS. By Lt.-Col. T. H. GOODWIN, R.A.M.C., Author of Notes for Medical Officers on Field Service in India and Field Service Notes for R.A.M.C., with an Introductory Note by Surgeon-General WILLIAM C. GORGAS, U. S. A. Philadelphia and New York: Lea & Febiger, 1917.

THE contents of this little volume of coat pocket size are elaborated from a series of lectures given by the author before the classes at the Army Medical School at Washington, D. C. There are chapters on Organization and Administration, War Surgery and Sanitation in War, with a brief Appendix on General Notes for Service on the Western Front. The consideration of all these subjects is compressed into 107 pages, which also contain 34 text figures, and the entire instruction comprises not over 20,000 words.

LE COURAGE. Par MM. les docteurs LOUIS HUOT, Médecin principal de 1^{re} classe des troupes coloniales, Médecin divisionnaire, et PAUL VOIVENEL, Aide-major au 6^e bataillon du Régiment d'Infanterie. Préface de M. EUGÈNE ÉTIENNE, ancien Ministre de la Guerre. Prix, 3 francs 85. Paris: Félix Alcan, 1917.

THIS little volume, devoted to the psychology of courage, begins with a chapter on war, which is followed by a defense of the claim that courage is purely a human quality, "animal courage" being a misnomer. The elements which enter into the conception of courage are then individually considered—fear as its background, altruism, habit and experience, love of taking a chance, crowd courage, love of country, courage in battle and finally pathological courage. The work is rich in citations from authors, touching upon acts of bravery by real and fictitious characters. Among romancers who deal with courage Stephen Crane is mentioned. Professional courage naturally enters largely into the general subject. Crowd courage is the inversion of panic fear. Fatalism does not receive a separate consideration, but is properly credited as a factor in individual courage. The book is worthy of a translation and should be widely read.

WAR-SHOCK. The Psychoneuroses in War; Psychology and Treatment. By M. D. EDER, B.Sc., Lond., M.R.C.S., L.R.C.P., Lond.; Late Temporary Captain, R.A.M.C., and Medical Officer in Charge of Psychoneurological Department, Malta. Price, \$1.75 net. Philadelphia: P. Blakiston's Son & Co., 1917.

THIS book is another contribution to the study of the war neuroses, often called shell shock. The author has presented 100 consecutive cases, with attempts to understand them from a psychogenetic standpoint; in these cases he could find "antebellum" causes, family or personal, in only thirty. He found suggestion under hypnotism his best weapon. Although, owing to service exigencies, he was able to apply psychoanalysis to only four cases, he approaches the problems presented on lines laid down by Freud and Jung, even to discussing the dreams of the patients. While this will at once damn his book in the minds of many, it should not be dismissed contemptuously. He has at least obtained some understanding of the mental mechanisms of these soldiers and has succeeded in curing or improving nearly all his cases. The book is a small, handy one and can be read by all with pleasure and benefit.

THE MICROSCOPE. An Introduction to Microscopic Methods and to Histology. By SIMON HENRY GAGE, Professor of Histology and Embryology, Emeritus in Cornell University. Twelfth Edition. Rewritten and illustrated by over 250 text figures. Price, \$3.00 net. The Comstock Publishing Co., 1917.

GAGE on the microscope is one of those works which seem to have existed always, so neatly does it fill its niche. The magic numeral "12" before the "edition" speaks volumes itself, showing the seekers after knowledge who have used it and found it good. Although there has not been such radical progress in microscopy in the past decade as has been the case in other sciences

allied to the medical, a number of noteworthy innovations have been included in the present volume. Chief of these are: (1) The development of the single objective binocular and the dark field illuminator; (2) the adaptation of the new powers of the electric light to the projection microscope; (3) the perfection of photographic light filters; and (4) the production of a glass filter. Microchemistry and metallography have been omitted from this edition as adequately dealt with elsewhere.

Dr. Gage describes the microscope simply, but in great detail; he discusses the appearance of objects in the microscopic field and then goes on to discuss micrometry, projection and photography, as well as the spectroscope and polariscope. The discussion of the preparation of material for microscopic examination is devoted to novelties and variations in lenses and microscopes. A complete bibliography is appended and the work is well indexed.

The physician who goes in for laboratory work at all cannot dispense with this book; and even if he take but an academic interest in the subject he will find it invaluable. We think it should be the first selection for the laboratory library. The illustrations are excellent and the book is splendidly gotten up from a mechanical viewpoint.

STATE BOARD EXAMINATION QUESTIONS AND ANSWERS OF THE UNITED STATES AND CANADA. A Practical Work Giving Authentic Questions and Authoritative Answers in Full That Will Prove Helpful in Passing State Board Examinations. Reprinted from the MEDICAL RECORD. Fifth Edition. Altogether New Matter. Every Question Answered in Full. Price, \$2.50. New York: William Wood & Company, 1918.

THIS is the fifth edition of a very useful book. That it is considered a useful book is proved by the fact of four editions having been exhausted. The object of publishing the State Board Examination Questions and Answers which have appeared from time to time in the MEDICAL RECORD is to acquaint the student with the general tenor of such papers and thus to inspire him with confidence. The unknown always possesses terrors, but when the student knows what to expect in the written examinations they are divested of much of their dread.

ELEMENTS OF PEDIATRICS FOR MEDICAL STUDENTS. By ROWLAND GODFREY FREEMAN, A.B., M.D., Adjunct Professor of Pediatrics, New York University and Bellevue Hospital Medical School; Attending Pediatricist to the Roosevelt Hospital, New York, etc.; ex-President of the American Pediatric Society. Price, \$2. New York: The Macmillan Co., 1917.

THERE has long been wanted in the study of pediatrics a work which would deal with the standards of the normal child on which to lay a foundation for the future comparison of abnormal conditions which engross pathological pediatrics. Practically all of the comprehensive works on the diseases of children give a certain number of pages to the normal child anatomy, physiology, and development, but it has remained for Dr. Freeman to supply in every detail a book devoted wholly to the normal child.

This modest-sized volume is written primarily for students, but there is no reason why it should not prove delightful reading for all medical people who have more or less the care of infants and children in their keeping. It is one thing to have a scattered knowledge of the infant world in one's mind, but it is a more beneficial matter to have that knowledge brought into proper order and sequence as it is arranged in this latest contribution to normal pediatrics.

Aside from all the usual aspects expected in the study of infants, the author has dealt with the care of premature children and the mental and moral development of children in general. One, on reading these later chapters, wishes that Dr. Freeman had added more pages to this special part of his book, for, after all, the physical upbuilding of a child is but a preliminary to his mental and moral development, and a keener insight into this side of the child life would give to the coming pediatricist a sympathy and understanding which would go a great distance toward his success in this, his chosen field.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

21st Regular Meeting, Held Jan. 4, 1918.

THE PRESIDENT, DR. GORHAM BACON, IN THE CHAIR.

The Problem That Mental Disorders Present to the Medical Profession, and the Profession's Responsibility.—

Dr. WALTER B. JAMES read this paper (see page 353).

Dr. M. ALLEN STARR said that the paper had been of a great deal of interest and brought up many important points. In the first place he wished to speak about instruction on the subject of insanity. When he began to teach medicine thirty years ago at the College of Physicians and Surgeons, in laying out the course on nervous and mental diseases, he assigned about one-quarter of the time to mental disorders and as it was then impossible to give clinical instruction in that subject, he dealt with it in didactic lectures, which appeared to awaken much interest among the students. There being a lack of suitable textbooks he had to publish a synopsis of these lectures, which included considerable elementary psychology. As time went on the increased amount of work involved in medical education crowded upon the subjects of neurology and psychiatry so that twelve years ago it became necessary to reduce the time assigned to these subjects one-half. Later the lectures upon insanity were cut out and a scheme of instruction by clinics at Bellevue Hospital was substituted. These clinics were optional and the students did not attend. He believed at present that eight clinics were held in this subject of insanity in the course of the four years' instruction. He believed this method to be very imperfect, as a student who had no knowledge of psychology could not understand a clinic on insanity and got nothing out of such a clinic. Dr. James had brought this point out very cleverly. A student could not appreciate the symptoms of an insane person when he knew nothing about the normal action of the mind and this knowledge he could not obtain from a clinic, but must get from a didactic lecture or from a textbook. One might just as well expect a student to make a correct diagnosis of pneumonia when he had no knowledge of physical diagnosis. Instruction in insanity should be didactic at first and should include elementary psychology. In the second place he wished to add that Dr. James' paper recalled to mind a paper read by Dr. S. Weir Mitchell some years ago which caused a great amount of criticism among men working in psychiatry, and what Dr. Mitchell said at that time, namely, that very little information on or contribution to the subject of insanity had come out of the insane asylums of this country. The men who were working in the insane asylums were not trained in laboratory methods until within the last few years, and even those who had been trained in these methods had many of them failed to apply them to the study of their cases. It was his belief that a considerable proportion of cases of insanity were due to poisons circulating in the blood and originating in the body from errors of metabolism or defects in the action of the ductless glands, but he failed to find any systematic investigations along these lines in any of the insane asylum reports published in this country with one or two exceptions. Cannon and Crile had demonstrated conclusively that certain physical conditions were produced in the body by fear and anger. In addition to the rapid action of the heart and respiration and the increased secretion of the sweat glands, they had shown that the effect of emotion was to increase the secretion of the suprarenal glands in such a way as to increase the production of glycogen in the liver and also in the muscles, thus producing a muscular energy which enabled an animal in a state of fear or in a state of anger to fight or run away. The display of muscular energy in a maniac, which was known to be enormously greater than that in a sane man, had proved that the excitement of fear and anger in the insane produced similar chemical changes, increasing the muscular activity. This was only one example of the chemical change occurring in insanity, but there was no place in this country where these chemical changes connected with mental processes had been or could be investigated, and it had been impossible for

him to induce the authorities at the Phipps Institute in Baltimore to understand these chemical investigations. He had now three cases in mind of states of depression undoubtedly due to errors in the chemistry of the system, in two of these there was probably a defective secretion of the thyroid gland and such investigations might easily lead to the discovery of proper remedies, but he knew of no place where such investigations could be made. Psychiatric hospitals should be established with clinical laboratory observers connected with them and only with these could we hope to see our asylums made of some service in the study of insanity. At present the asylum received the cases in the last stages only. If only cases which had large cavities in the lungs went to the sanatoria for tuberculosis sanatorium cures would not be expected. If mental diseases were taken in the early stage and properly investigated and treated, we might hope for a large percentage of cures at the present time. Considerable attention was being given to psychoanalysis, but the experience of the last five years had shown pretty conclusively that, however interesting this might be to the psychologist, it was of no practical importance in the treatment of patients. If this paper of Dr. James' awakened an interest in chemical and laboratory research in mental disorders it would open the way for great advances in the therapeutics of insanity.

Dr. BIGGS said it had been his experience for a good many years in public health work that while public authorities seemed unwilling to make opportunities for laboratory work, as a matter of fact this was not so. If one only showed the usefulness of the laboratory work, appropriations were available in constantly increasing quantities. That was the experience in New York City, and it had been his experience in the State Department of Health. Less than four years ago, we had a State Laboratory that did not deserve the name, since Dr. Wadsworth was appointed director of the laboratory, it had been reorganized and was now doing very good work. The appropriations had increased from \$30,000 a year to \$175,000. This simply showed what was possible if the usefulness of the work was only demonstrated. If one only had a man at the head of the work who had energy and ability, he could get the money to do the work.

Dr. DANA expressed his strong appreciation of the views which Dr. James had presented, and he hoped that his paper would make the general medical man take a keener interest, and hold in higher value the science of psychiatry. He believed in teaching psychiatry in medical schools. He said that there were two kinds of psychology—the static and the dynamic, and there was great difference of opinion just now as to which was the valuable one and which should be taught to medical students. He himself believed that both kinds would be of service. With regard to mental hygiene and the prevention of mental diseases the speaker thought that the greatest effort should be made toward reclaiming people before they had ever got into State hospitals. When a person had reached the stage of mental disease or deterioration that he required custodial care, preventive medicine could not do its best work. He thought that preventive medicine should attack, for example, the general paresis before it became general paresis, and if the State were to take an active interest in this phase it could reduce the 20 per cent of the insane suffering from general paresis to 5 or 10 per cent. The group of patients known as sufferers from psychoneuroses, hysterias, neurasthenias, and psychasthenias, formed all the group in which most could be done in the prevention of insanity.

Dr. FORDYCE said that he was glad that Dr. Dana had called attention to the possible prevention of paresis by systematic examination of the spinal fluid. This question had interested him for a long time and he believed that if syphilis was properly controlled by an examination of the spinal fluid before the patient was finally discharged it might be possible to diagnose paresis long before stigmata of degeneration appeared. In the first year of syphilis it was found that from 25 to 30 per cent of the patients showed spinal fluid changes. In some of these patients the colloidal gold test gave a paretic curve and the Wassermann reaction was strongly positive in the high dilutions. At this stage it was quite possible to anticipate by proper treat-

ment the development of the late degenerative results of the disease.

Dr. GILMAN THOMPSON said he would like to add his testimony to the great value of elementary training in the matter of psychiatry. As a student he had received no instruction in this subject at all, but after graduation he had been fortunate in securing a service for some time in the Bloomingdale Asylum, and it had been of great value to him ever since, for there were so many applications of a knowledge of psychiatry in general medical practice. He was much interested in the plea that Dr. Starr made for didactic instruction, not only in this subject, but in others. It was certainly a good way to teach this subject to students. It seemed that what was needed was more graduation instruction in insanity, but those who had sat on medical faculties knew that there was very little time to give to this topic, no matter how important it might be. When we had reached a five years' course of medical college training, there would be opportunity given for this line of instruction, and it should have ample recognition. Formerly there was a full-fledged psychiatric laboratory in New York City, in connection with the New York Infirmary for Women and Children. The trustees of the Infirmary found themselves in possession of a large building, which they equipped for the purpose. A few patients were treated, but the institution gradually died on account of lack of financial and professional support, and had not been in existence for some time.

Dr. KIRBY said there was no doubt that the past ten or fifteen years had witnessed a notable advance in the medical and psychiatric work in State hospitals and other institutions dealing with mental disorders. Scientific methods of approach to the problems of psychiatry were being gradually developed and the great social significance of mental abnormality was slowly but surely winning a general recognition. Unfortunately it was true, as Dr. James had so clearly pointed out, that the general profession had not shown any decided interest in the applications of the newer psychiatry, although these applications led directly back to the field occupied by the general practitioner. The reasons for this were not difficult to find. The ancient aversion of people to contact with the mentally sick was still shared by physicians who moreover had always been to a very large extent relieved of all responsibility in the care and treatment of mental cases on account of the State's practical monopoly of the management of mental disorders as soon as any pronounced symptoms appeared. A most encouraging sign was the passing of the isolation of the State hospitals and their establishment of various contacts with the community and the medical profession. The hospitals were now not only receiving many voluntary patients, but out-patient clinics and dispensaries had been established and manned in various localities by the State institutions. The cumbersome legal machinery surrounding the admission of most patients to a State hospital might be with great advantage still further modified; also the internal arrangements of State institutions should in the future be designed not chiefly for the relatively small class of turbulent cases, but for the larger class of easily controlled cases who required little more than the kind of restriction imposed by general hospitals. An entire change in the present methods of the teaching of psychiatry was, as Dr. James had shown, urgently needed. Didactic lectures would, of course, be required, but the great difficulty in teaching had been that students could not be shown clinical material of the kind that would interest a man preparing himself for general practice. Very pronounced mental cases brought from a State hospital to an amphitheater and shown to students usually afforded the latter some diversion but did not appeal to them as a problem in general practice. The recognition and treatment of incipient psychoses and borderland cases rather than of committed patients should be emphasized in clinical instruction. Such material was usually not available because physicians and general dispensaries did not devote much time to such cases. It was obvious that a psychopathic hospital would more than any other thing remedy this defect in our teaching facilities and bring psychiatry more into line with other branches of medicine.

Dr. JAMES, in closing the discussion, said that he had been delighted with the interest that the members of

the Practitioners' Society had shown in this subject, and could only wish that the interest of the medical profession at large was as keen. After spending the summer with the State Hospital Development Commission he had been impressed with the fact that it was the legislators and the more intelligent portion of the public generally that interested themselves in the problem of the insane and of insanity, rather than the medical profession. The lay members of the commission, including some of the busiest and most prominent legislators at Albany, had given their time and strength to this work ungrudgingly, and in a way that he confessed had surprised him. He had been surprised also by the intelligent interest shown by the boards of managers of the State hospitals for the insane, and as soon as our own profession threw itself heart and soul into this problem he believed that we should have taken a long step forward towards its solution. He believed that the legislature and the people generally were prepared to do anything for the insane that was seriously recommended by our profession, and also to do anything reasonable looking towards the solution of the whole problem of insanity. He was interested in what Dr. Biggs had said about his suggestion of making a knowledge of psychology requisite to entrance into a medical school, or, as an alternative, the teaching of psychology in the school itself. This he confessed seemed to him so obvious as hardly to need further emphasis. Today a man graduated from the medical school had hardly heard the word psychology. It had seemed to him that the constitution of our medical schools was a wrong rule. We retained still too many of the features that were inherent in the old-fashioned proprietary school, belonging as it did absolutely to a little group of professors and looking to them alone for its stimulus and guidance. Each one of these men fought fiercely for the welfare and advancement of his own department, and the strongest of them secured most of the curriculum. There was hardly any other life that did so much to stunt the imaginative faculty and the breadth of mental vision as the life of the teacher, and when our medical schools came to be governed more directly than at present by boards of trustees, who, taking a bird's-eye view of the situation would be able, with advice, to see the part which each chair should occupy in the curriculum, he believed that medical education would have taken a distinct step forward. Anatomy, human and comparative, would absorb less of the time and interest of the students, and more time would be given to the study of function, normal and pathological, and especially the functions of the mind. Of course a psychopathic hospital was needed in New York, and needed badly, and he was glad to see that all present recognized this fact. Whenever a united medical profession asked for it and was even approximately in accord as to what it wanted it was his belief, as a result of last summer's work, that its accomplishment would be only a matter of a short time. Our profession probably carried more weight in public life than most of us realized and if we could cease differing upon unimportant, and present a reasonable united front upon essential matters, we should achieve the accomplishment of what after all must be the desire of every real physician—success in our combat with disease of every description.

Acute Dilatation of the Stomach in Pneumonia.—Dr. LEWIS A. CONNER presented this case. He said that the subject of acute dilatation of the stomach was now such a familiar one that he would not have ventured to report this case had it not seemed to him to throw some light upon one of the gravest and most intractable complications of lobar pneumonia, namely, marked abdominal distention. He knew of no complication of pneumonia more serious in its import or more resistant to treatment than such distention. Usually this tympanites seemed to involve a great part of the gastrointestinal tract and results in a uniform hemispherical distention of the whole abdomen. The present report concerned a man some forty years of age who entered the New York Hospital a month ago on the third day of his pneumonia. He looked very ill and was beginning to show some abdominal rigidity and distention which in spite of treatment increased rapidly. On the next day when Dr. Conner saw him his condition had become very much worse; there was well marked pulmonary edema with cyanosis, and it was quite evident

that the man had only a few hours to live. Examination of the abdomen showed very marked distention, which, however, differed from that usually found in that the distention was much more pronounced in the upper than in the lower half of the abdomen and that by careful palpation one could recognize that the lower limit of the distention was sharply circumscribed and had a curved outline strongly suggestive of the greater curvature of an enormously enlarged stomach which occupied the whole upper half of the abdomen and extended downward to a point 5 cm. below the umbilicus. In spite of the fact that there had been no vomiting it was quite evident that there existed an acute dilatation of the stomach of formidable size. Although the man's condition seemed hopeless it was deemed wise to attempt to empty the stomach and this was done by passing through the nose a very small sized stomach tube. This was accomplished with very little disturbance to the patient and resulted in the escape of an enormous quantity of gas and the removal of almost a quart of dark colored liquid. The abdominal distention disappeared entirely and there was an appreciable relief to the embarrassment of respiration, although no improvement to the condition of the pulmonary edema, which steadily increased and the patient died some six hours later.

Acute dilatation of the stomach was known to occur occasionally in the course of lobar pneumonia and its pathogenesis in that condition was no less obscure than was that of other more common formas. It was, however, far less frequent than the corresponding distention and dilatation of the intestines. As far as the speaker knew, it had never been suggested that the stomach might participate in the severe form of tympanites which constituted such a grave complication of lobar pneumonia. The occurrence in this case, however, suggested that such a gaseous distention of the stomach might sometimes at least play a part in such tympanites and that the relief of the stomach inflation by means of the stomach tube might aid materially in overcoming the general tympanites. The passage of the stomach tube even in such gravely ill patients could be accomplished with very little discomfort or embarrassment to the patient if a very small tube was used and if the tube was passed through the nose rather than through the mouth.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held December 21, 1917.

THE SECOND VICE-PRESIDENT, DR. LUDWIG KAST, IN THE CHAIR.

The Principles and Technique of the Treatment of Wounds.—Dr. GEORGE LOEWY of the Medical Corps of the French Army, assigned to the Rockefeller Institute of Medical Research, made this presentation by invitation, which consisted in a description of Carrel's method of treating wounds (see MEDICAL RECORD, November 3, 1917), illustrated by lantern slides and moving pictures. Attention was directed more particularly to the more recent developments and details of this method. In these moving pictures, which were taken at the War Demonstration Hospital of the Rockefeller Institute, Dr. Carrel had emphasized the way in which wounds should be treated and he started by showing what should be the aim of the surgeon, namely, to sterilize the wound before suppuration took place, or when suppuration had supervened to arrest it, to sterilize the wound, and to close it. In order to accomplish these aims treatment must be begun as early as possible. The first two pictures would illustrate that it was possible to accomplish much more by this method than had previously been done by former methods of treatment. The first picture was that of a wound of the forearm which was closed at Carrel's hospital after five days of treatment, and in which a perfect functional result was obtained. The second picture showed a wound closed after seven days of treatment. The results obtained at the beginning of the war were very bad because they were poorly organized for the work and because the pathological condition of the wounds was absolutely unknown. It was surprising how little progress had been made in the treatment of war wounds

from the time of the Civil War until 1914. If laboratory work had been done during the interim of fifty years, if the pathology of the wound and the topography of the infection had been studied, an entire year would not have been wasted in efforts to cope with the problems which confronted them during the first year of the war. The condition of the surgeon could be compared with that of the chemist before the end of the eighteenth century. At that time the chemist became interested in the use of the scale or balance and measured the weights of the substances involved in the chemical reaction. From that started the wonderful growth of chemistry. In surgery these quantitative measures must be used; the use of precise methods was most important in every field of surgery. Therefore, in the film, after the purpose of the author, was shown the basis of his method of surgery. The basis of Dr. Carrel's method was not a chemical substance or any special procedure; it was the method by which the volume of infection and the action of chemical and surgical procedures on the healing of the wound could be measured or expressed in figures, or plotted in curves. The action on infection was measured by counting bacteria in the secretions of wounds. The numbers of bacteria per microscopical field were recorded on a chart, like a temperature chart. Every two days the bacterial curve was plotted. Each patient had a bacterial chart which indicated the state of infection. The action of a given procedure was shown by changes in the bacterial count. For example, a drop of the bacterial count from 40 bacteria in a field to one bacterium per ten fields indicated surgical sepsis. The bacteriological curve showed whether sterilization progressed properly, and when the wound should be closed. Sterilizing procedures must not injure the tissues. The best method of testing their action on tissues was to study their influence on cicatrization. In order to study the process of cicatrization, a technique for measuring accurately the area of wounds was developed. Sterilized cellophane was applied to the wound and the edge was outlined with a wax pencil. This drawing was transferred in ink to an ordinary sheet of paper. Afterward the area was measured by means of a planimeter, either the Amsler system or some other. A curve was obtained by carrying the area, in square centimeters, in ordinates, and the time, in days, in abscissæ. In many experiments made by Dr. Carrel the curve representing the cicatrization of aseptic wounds was of regular and geometric appearance. These curves were expressed by a mathematical equation in function of time and area. After a large number of slightly infected wounds had been studied, a simple extrapolation formula was obtained. Marked deviation from the calculated curve showed generally that infection had set in. By means of the formula the area of the wound after a given time could be foreseen. The action on cicatrization of sterilizing procedures was ascertained finally by comparison of observed curves and calculated curves. By these measurements an exact comparison could be made of the value of different procedures, surgical, mechanical or chemical, and the best selected. The aim and the two main methods upon which the technique was based were emphasized in these moving pictures in order to turn the mind of the surgeon to the necessity of using methods by which they could measure what they were doing, know when a mistake is made, and know when they are doing the right thing by actual mathematical measurements. This part of the film was the only new part of the whole method and was the cause of the enormous progress in practical results. After an understanding of the general principles, the surgeon could comprehend the details which were described in the second part of the film. This part showed the practical way of taking care of the wound; a combination of mechanical and chemical procedures used under bacteriological control, until the wound was sterile and closed. Dr. Loewy then gave a moving picture demonstration, showing the method of mechanical sterilization for fresh, sterile wounds. It was, of course, most artificial, but the idea was to show the different stages as, for instance, free incision of skin, aponeurosis, and muscles, excision of necrotic edges of skin, excision of the bruised portions of the tract (necrotic fragments of muscles being carefully removed), removal of shell fragments and shreds of

clothing. Hemostasis was carefully carried out. A sufficient degree of asepsis might be reached through mechanical cleansing to allow immediate stitching, but this must be done only under special conditions. Too often it was not possible to practice early intervention; a state of shock or difficulties of transportation might prevent operation for some time and the infection might spread during this time. On the other hand, the local condition might prevent complete cleansing, for instance, the proximity to important vessels or nerves. Another point was that an operation such as this required time and was difficult to perform. Practical difficulties, when the doctor was exposed to the same dangers as the soldiers, prevented the necessary precision in the Advanced Surgical Unit. For these reasons the wound remained septic and it was of prime importance to disinfect the wound with chemical substances. The existence in the wound of the remaining contused parts explained the necessity of *chemical sterilization* and the use of an antiseptic having the property of dissolving necrotic tissue. And this was the principal reason why Dr. Carrel used hypochlorite of soda instead of chloramine, which did not possess this dissolving property. The antiseptic was only an instrument, like a scalpel in a surgical operation. Dakin's solution and chloramine-T were generally used, but Dr. Carrel said that other substances could also be employed just as an operation was performed with several different instruments.

The doctor showed the method of the preparation of the hypochlorite and of stabilizing it with potassium permanganate and also its preparation by bubbling liquid chlorine through sodium carbonate. He also described the Daufresne paste, made by mixing Dakin's chloramine-T with sodium stearate. This paste gave up the antiseptic substance slowly and was only suitable for surface wounds which it sometimes sterilized in twenty-four hours though it usually took longer in war wounds. Demonstration was made of the arrangement of the irrigating tubes, the closure of wounds after the sterilization had been obtained, and a hammock suspension apparatus which enabled a patient with a fracture of the thigh to move about in bed. In addition he showed Dr. Carrel's method of skin grafting applicable to large surface wounds. In conclusion the speaker said that Dr. Carrel showed that the entire method of wound treatment was like a chain in which each procedure was a link. It was not the use of a paste, it was not the use of an oil, or of any mechanical cleansing. It was a combination of procedures under a definite control which would give the results, and it was impossible to suppress any one without the suppression of all.

In conclusion, Dr. Loewy said that the method was no longer in an experimental stage. It had been absolutely proved by thousands of cases. He referred to the report of Captain Campbell and Major Wolfenden (*Lancet*, August 11, 1917) on gunshot wounds of the knee joint. Comparing the former results with those obtained recently by Carrel's method, these surgeons found that in the latter the mortality was reduced one-fourth and that the number of cases requiring amputation was reduced one-eighth, and all this in spite of the fact that the cases treated by the Carrel method were if anything more severe. Dr. Loewy emphasized the convictions of all those who had had experience with the method, to the effect that, as stated in the report of the surgical committee to the Director-General of the British Army Medical Service, which appeared in the *British Medical Journal*, November 3, 1917, it would (1) diminish the dangers incidental to sepsis, including secondary hemorrhage; (2) hasten the patient's convalescence; (3) lessen the liability to stiff joints and cicatricial deformities; (4) enable the patients to leave the hospital with better general health than they otherwise might, and (5) where secondary operations became necessary these operations were more likely to be free from septic complications than where some other system of primary treatment had been adopted.

Dr. EDWARD WALLACE LEE told of his impressions of the value of the Carrel method of treating wounds as it was being demonstrated at the Rockefeller Hospital for Teaching War Surgery. For those who had not had the privilege of seeing the actual work as it was being carried out in this institution under Drs. Carrel and

Loewy and those connected with the hospital it certainly was a great privilege to have seen the pictures which Dr. Loewy had shown tonight. Dr. Lee said he had spent three months studying the technique of this method at the Rockefeller War Hospital and had been making daily observations of the results obtained by it. Words were not adequate to express the enthusiasm he felt for the work he had seen done in that institution. He did not believe in marvels, but the marvelous things he had seen there were beyond conception, and he had had thirty years' experience in surgery and thought he was quite well informed in antiseptics and asepsis. He had started in practice when antiseptics was first being used and had watched the progress of developments along this line for thirty years, but until now he had seen nothing that gave the results that were obtained by the Carrel method as it was carried out at the Rockefeller Hospital. The cases that they got there were those that had been under the observation of good men in this city and throughout the country, and had been treated for periods varying from five days to fifteen years, and the results obtained were most remarkable. For instance, in a case of old osteomyelitis, which had been intractable to treatment for a long period, it was gratifying to see the results obtained by the Carrel method. Dr. Lee said he had not the time or the inclination to go into details, but he would say that if anyone was not enthusiastic and did not believe all that was claimed for this method, all he had to do was to carry out the method in detail in order to be convinced. It did not mean going to the druggist and getting a prepared antiseptic, but it meant carrying out the entire technique accurately from the time the patient entered the hospital until he left. They healed wounds with mathematical precision, even in exact conformity with an algebraic formula. The plan might appear a little complicated until one became familiar with it and then it seemed very simple. Another point worth mentioning was the results obtained in empyema following pneumonia. He had seen these demonstrated not only in the Rockefeller Hospital but elsewhere as well. Even the best men had not realized that pleurisy with effusion developed in the early stages of pneumonia, even before the crisis was reached. In these cases of empyema, he had seen a rib resection, the pus evacuated, the cavity irrigated with the proper solutions, and the patient had recovered in a remarkably short time, even within two or three weeks.

In closing, Dr. Lee moved that a vote of thanks be extended to Dr. Loewy for having presented this work to the Society. This motion was unanimously carried.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 17, 1918.

THE VICE-PRESIDENT, DR. EDWIN B. CRAGIN, IN THE CHAIR.

Hay Fever and Asthma and the Uses and Limitations of Desensitization.—Dr. ROBERT A. COOKE presented this paper in which he analyzed a series of cases in the hope that they might furnish a more definite viewpoint, first, as to the extent to which anaphylaxis played an etiological part and, second, as to the results that accrued to the patient from observations so made, and, finally, the indications for and the limitations of treatment by desensitization in hay fever and asthma. He discussed briefly relative immunity to infectious diseases for the purpose of emphasizing the fundamental identity of the body reactions to proteins, whether they were bacterial proteins, or toxins, or inanimate proteins, and the fact that whereas this sensitization of body cells was distinctly advantageous and protective against the incidental invasions of bacteria, it was a definite cause of disease and absolutely disadvantageous to the human economy when this same capacity for sensitization of cells had spread to those forms of inanimate proteins which constituted our daily food, or with which we must come in intimate contact. Dr. Cooke then reviewed the principles of sensitization in general and noted the following facts as having been experimentally established: (1) The injection of any protein into an animal stimulated the body cells of that animal to produce specific reacting substances called antibodies. (2) An incuba-

tion period was required for the formation of antibodies against these proteins in exactly the same way that an incubation period was required in infectious diseases. (3) The production of antibodies bore a definite relation to the amount of protein injected and the number of times that the injection occurred. These antibodies tended to attach themselves to certain cells within the body and also to circulate free. When antibodies were present in small amount they tended for the most part to attach themselves to cells. When an overproduction of antibodies had been stimulated, they existed in both forms, attached and free. (4) On introduction of the specific protein into a sensitized animal, a reaction occurred and this reaction took place in the sensitized cells. (5) Sensitization and immunity were in principle identical. When antibodies were few and attached we had the sensitized state; when they were in excess and circulated free in the blood we had the immune state. Immunity, however, was only relative and depended upon the number of free antibodies present. Reactions depended not only on the amount of the intoxicating protein that was introduced, but on the manner of its introduction. By this was meant that an animal might be immune to a subcutaneous injection, whereas the same amount of protein intravenously introduced would cause death. (6) Immunity produced experimentally and due to the free circulation of antibodies was only a temporary state, and in the absence of stimulation to its continuation by specific injections would return to the sensitized state and the free bodies practically disappear from the blood. The essayist then discussed artificial versus natural sensitization, stating that artificial sensitization never reached the degree of exquisiteness that was discovered by those naturally sensitized. Neither was artificial sensitization as permanent as natural sensitization nor did it seem to give rise to clinical manifestations. When one bore in mind that the anaphylactic reaction was cellular in character it could well be understood that in the sensitized individual the clinical reaction that ensued upon the introduction of the specific protein would depend entirely upon the group of cells that happened to be sensitized, and it was for this reason that we saw such a miscellaneous and apparently irrelevant group of symptoms described as being anaphylactic in nature. On account of the fact that the field was so new, one felt tempted, and rightly, he believed, to apply this principle to many of the undetermined ailments of the present day, such as migraine, epilepsy, arthritis, renal, and hepatic diseases, and even to some of the blood dyscrasias because of the fact that certain of these manifestations were seen in experimental work. As to the pathogenesis of sensitization but little was positively known. The writer and Dr. VanderVeer, in a former publication, had been able to show: (1) That 50 per cent. of the cases of sensitization had a positive family history, whereas only 14 per cent. of a group of normal individuals gave such a history. (2) That the age of onset of the clinical symptoms was earlier in cases with a positive family history, the earliness of onset being in direct ratio to the completeness of the family sensitization. (3) The clinical manifestation of this sensitization in the descendant bore no relation whatever to that of the antecedent. In other words, sensitized individuals transmitted not a specific sensitization, but an unusual capacity for developing bioplastic activity to any foreign protein. (4) In so far as it was possible to discover in the human race, the possibility for sensitization was transmitted as a dominant characteristic in the Mendelian sense of the word. One must also consider whether those humans who had inherited this abnormal characteristic developed their own sensitization by the usual immunological process, or whether the sensitization was acquired in the absence of antigen. Arguments in support of the latter contention were presented.

Multiple Sensitization.—The peculiar capacity of individuals to develop reacting bodies within themselves was shown most strikingly in the fact that over 42 per cent. of a large series of cases showed a reaction to many unrelated forms of protein, these different sensitizations amounting to as many as fifty in some cases, and showing absolutely no relation to one another. The clinical diagnosis of sensitization depended upon

the production of a reaction. These reactions depended upon the presentation of a suspected protein to the sensitized cell. It must be borne in mind that the sensitized cells were much more widely distributed than the particular group giving a clinical reaction. To this rule there were some exceptions. In view of the fact that sensitization was not limited to any particular group of cells, but seemed to affect all of the epiblastic tissue in general, it was possible to make use of this reaction in the diagnosis and we had recourse, therefore, to the intradermal and to the ophthalmic reactions. The essayist gave preference to the intradermal test by the hypodermic for the reason that it created less trauma and the protein was brought into more intimate contact with the sensitized cells. Approximately 1/100 c.c. was injected. Usually the reaction was observed in fifteen or twenty minutes, though occasionally it was deferred twelve to twenty-four hours. The ophthalmic test was made by instilling a small amount of the solution into the eye. The reaction began within fifteen minutes and was characterized by itching, lacrymation, and conjunctival and corneal injection. This reaction was more limited in its value than the intradermal for the reason that many of the food proteins that gave clinical symptoms and a cutaneous reaction gave no ophthalmic reaction. Those cases that required a high concentration of protein to produce a reaction were much less sensitive.

Hay Fever.—In discussing hay fever the essayist protested against the use of the term hay fever as too restricted in its meaning to fulfill all the requirements and convey the conception of the condition of rhinitis as it was understood today. He suggested the term "protein rhinitis" or anaphylactic rhinitis to cover the group of disturbances due to pollens, animal emanations, perfumes, sachets, and foods. The more one studied clinically the so-called vasomotor rhinitis the larger became the percentage of cases that were demonstrably anaphylactic. He did not wish to be understood as assuming a too biased attitude or denying the existence of vasomotor changes *per se*, but he believed the same situation obtained here as in bronchial asthma, namely that there was a development of a capacity in the mucous membrane to react by vasomotor changes to exciting causes other than those fundamentally responsible for the condition. A consideration of the pathogenesis and pathology of protein rhinitis led the writer to the conclusion that spontaneous sensitization occurred in human individuals rather than a process of sensitization by the usual immunological process. A consideration of the importance of anatomical structure and infections made it seem fair to assume the hypertrophied and chronically congested mucous membrane was the result of either infection or protein reaction. Persistent protein reaction undoubtedly led to infection and its attendant symptoms.

The Etiology of Protein Rhinitis.—The essayist presented the following classification of the etiology of acute or chronic rhinitis: (1) Infective. (2) Non-infective. The noninfective might be (a) vasomotor rhinitis or (b) "protein rhinitis." A protein rhinitis might be due to (a) pollens, (b) sachets, (c) animal dander, (d) foods. Of these latter the pollens were the most important. Food was usually not a factor in the etiology of protein rhinitis; when food was a factor, gastrointestinal and cutaneous symptoms were also present and minimized or obscured the nasal symptoms. In making the diagnosis of protein rhinitis, if violent reactions were avoided it was feasible to make fifteen or twenty cutaneous tests at one time; ophthalmic tests to this extent were out of the question.

Treatment of Protein Rhinitis.—In the treatment of protein rhinitis three factors must always be borne in mind: (1) Sensitization. (2) The condition of the nose from polyp, hypertrophy of the turbinates, deviated septa, etc. (3) Infections, nasal or paranasal sinuses. The treatment of hay fever was carried out by the minute injections of the specifically reacting protein. It was best instituted six weeks before the onset of the trouble, one injection a week being given in gradually increasing doses. The injections were continued through the season, about twelve being given. If the symptoms had started, an injection of pollen extract was given every day for three or four days and

then every two or three days, gradually increasing the interval as the doses were increased. The result of the treatment in typical hay fever was evidenced by the fact that 80 per cent. of the cases were relieved of 80 per cent. of their symptoms. There were difficulties encountered in the administration of the pollen extract, either from too large a desensitizing dose or from insufficient dosage. Care in determining the degree of sensitization and experience were both invaluable in avoiding the danger inherent in this method of treatment. Where it was possible to alter the environment of the patient this method was preferable.

Etiology of Bronchial Asthma.—The essayist also presented a classification of bronchial asthma on an etiological basis as follows: A. Bronchial asthma due to anaphylactic absorption from (1) the respiratory tract, as animal and vegetable emanations; (2) the intestinal tract (foods); (3) foci of infection; (4) subcutaneous tissue. B. Bronchial asthma not due to anaphylactic absorption, as that due to thymic enlargement, tuberculosis, renal disease, cardiac disease, bronchial infections acute or chronic. On account of the identity of the clinical manifestations in the latter conditions they must always be borne in mind in making a differential diagnosis. In addition to the causes here classified, mention might be made of inciting causes such as physical exertion, over-eating, inhalation of irritating vapors and dust, and atmospheric and barometric changes. After discussing the pathogenesis and pathology of bronchial asthma, it was stated that the history of cases of chronic asthma led to the belief that the so-called vagotonic state to which attention had been directed was the result of repeated anaphylactic reactions, and that the asthmatic habit was one evidence of this heightened vagus tone. In the diagnosis of bronchial asthma all non-anaphylactic causes must be excluded and the cutaneous and ophthalmic tests were used as described in the paper in connection with the diagnosis of rhinitis.

Treatment of Bronchial Asthma.—Prevention was always indicated by avoidance of the cause of trouble if possible. In a series of 95 individuals with typical hay-fever and asthma caused by pollens, 18 of whom had both early and late forms, so making 113 cases, treated with specific pollen extracts, the fact was brought out that the asthmatic symptoms were controlled far more readily than the nasal manifestations. When the asthma was caused by sachets avoidance of the source of the trouble was always indicated; when it was due to foods avoidance of the antigenic foods should be the rule and desensitization only attempted when the reacting group included most of the foods habitually included in the daily diet. Foci of infection, wherever found, should, of course, be eradicated. Summing up the uses of desensitization it might be said that (1) first and foremost it was indicated in pollen rhinitis and asthma; (2) it was only indicated in the cases of sensitization to sachets, animal dander, and foods when avoidance of the antigenic substance was out of the question. The greatest limitation to the free use of desensitization was the grave danger not only to health but to life and its field of usefulness was automatically restricted by the fact that its effect was evanescent.

Dr. HERBERT S. CARTER said that it was with a good deal of hesitancy that he, as an internist, approached this subject, for the mere nomenclature was enough to make a stout heart quail. It was not only with the asthenic forms of anaphylaxis, such as asthma, hay-fever, and urticaria that they were concerned, but they would have to reckon with the less dramatic aspects of chronic anaphylaxis, and in studying this much depended upon what the laboratory men could teach them. Until their feet were placed on solid ground by Meltzer and other workers with the phenomenon of anaphylaxis it would be the football of all the specialists. Probably all the manifestations of this particolored disease belonged under one heading and when we knew all that there was to know of immunity we should have solved the problem of anaphylaxis to the full. Dr. Cooke had given such a complete picture of the subject of desensitization that he would not attempt to add to it, but would merely indicate some of the problems that faced the internist: (1) There were still certain cases of anaphylaxis, particularly the obscure asthmas, the knowledge of which left much to be desired. If in these

cases, after the full round of skin tests, no form of protein were found which gave a positive reaction, one found himself in much the same position as before he knew anything about anaphylaxis; he must fall back on empirical measures of forced elimination, etc. The mere failure to find the offending protein was no argument against the general hypothesis, but it left one with less faith in what he was doing. That was one problem, and a trying one it was. (2) By far the most important aspect of this question was the remote effect upon the parenchyma of the various organs that repeated acute or chronic anaphylactic shock might have. It was here that the particular interest of the internist lay, for in the solution of this question might lie the answer to many, if not most, of the so-called degenerative processes. There was a long list of workers who had added to their knowledge in this field, though the subject was of course only in its infancy. Gay and Southard had studied the effect of anaphylactic shock on the organs and had shown that hemorrhages were caused which were due to lesions of the capillary endothelium, that the changes in the capillaries of the endothelium were mostly fatty changes, waxy changes, or fragmentation of the heart and skeletal muscles, local necrosis of the epithelium, and round celled infiltration of the kidney as well as a thickening of the capsules of the glomeruli, as shown by Longcope. Longcope has also shown that in the heart the same necrosis, round celled infiltration, and scar tissue formation occurred producing the appearance of interstitial myocarditis. It was enough merely to mention these findings to show what a vast area of possibilities were opened. While these lesions were artificially produced by the repetition of repeated acute anaphylactic shocks, it was natural to ask themselves what the effect of repeated slight shocks might be even when too slight to cause any outward manifestation. In the fall of blood pressure consequent upon shock one could see great possibilities in the interpretation of acute subnormal blood pressure in acute infections, as, for instance, in a pneumonia which we had come to fear as an expression of depression of the vegetative nervous system, for while we commonly here put the blame on toxemia, the effect of a toxin on this system was ordinarily one of stimulation with raised blood pressure, as Pottenger had shown; while on the other hand we knew that the effect of anaphylactic phenomenon upon the vagus was one of depression. Manwaring had shown that the fall in blood pressure in the dog that accompanied anaphylaxis was not due to the direct action of foreign protein on the sensitized blood vessels but was probably an indirect phenomenon due to the explosive formation or liberation of depressive substances by the liver, resulting in vasodilatation, bronchodilatation with consequent fall in blood pressure and pulmonary edema. (3) As to desensitization, Dr. Carter said, his experience had been too limited to be of value, but the general impression was that a few of the patients who suffered from chronic anaphylaxis were entirely relieved, most of them were rendered more comfortable but were not free of symptoms, and some showed no relief. There was much to be desired in the way of sure promise of complete relief from symptoms. The efforts at desensitization were undoubtedly in the right direction, but there were still missing links in some of the chains.

Dr. OSCAR M. SCHLOSS stated that his experience with bronchial asthma was confined to cases of sensitization to food proteins seen in children. For statistical purposes these cases might be divided into two groups. In the first group the patients came under observation on account of a definite history of protein sensitization as indicated by such conditions as angioneurotic edema, and urticaria, and among these there were some cases of bronchial asthma. There were 42 such cases. The second group comprised 89 cases of bronchial asthma, and in these tests were made to ascertain their sensitiveness to food proteins. Of the 89 cases four gave positive reactions to the food proteins. It seemed that this furnished very definite evidence that bronchial asthma due to food protein was relatively rare. An investigation of the origin of this idiosyncrasy showed that it was either inherited or acquired. Dr. Cooke stated that in the cases that were artificially sensitized the state of sensitization was mild, and with this statement the investigations of Longcope were in

accord. Assuming that an acquired sensitization through ingestion might be taken in the same sense as artificial sensitization, Dr. Cooke's statement was not in accord with his own observations. In three cases of acquired sensitization in which the symptoms were of the most pronounced grade his reason for believing that the condition was acquired was that there was no family history and, secondly, there was a history of these children having ingested the food to which they later developed idiosyncrasy. When such a sensitizing dose was ingested it was usually some time before the toxic symptoms were manifested. Certain individuals seemed to be more easily sensitized at certain times than at other times. It had been brought out by Lust, Schloss, and Worthen, and others, that at certain times unaltered protein could pass unaltered through the gastrointestinal mucosa and produce sensitization. Wells' experience had some bearing on this subject. Wells found that certain groups of guinea-pigs could not be sensitized to a protein of a certain type, zein from corn, and he found that they had been fed corn previously. By carrying out his experiment he had been able to demonstrate that sensitization was acquired. Guinea-pigs fed for a certain time with white of egg passed through a stage of sensitization and later became immune; for a time they reacted very violently, and then if the food were continued they did not react and it was impossible to sensitize them actively to the egg white. There must be a previous predisposition to explain why relatively few people acquired sensitization of any marked degree. In a series of cases desensitization had been attempted by the speaker. He found it possible to desensitize such individuals by feeding the protein to which they were sensitive, but they must be fed with the protein frequently over a considerable period of time. His experience in this respect was in accord with that of Dr. Cooke. If, after having been desensitized, sensitization again occurred, it was present in a milder degree and could be more easily corrected. In cases of multiple sensitization the problem of desensitization resolved itself into that of desensitizing the patient to the foods to which he reacted most actively.

Dr. MARK J. GOTTLIEB related his experience with artificial desensitization which went to show that such artificial desensitization was not very prolonged. He also described an experiment on himself which seemed to indicate that serum carried over from one season to the next had not deteriorated. He thought it was possible to find sensitization in some cases in which there was no family history of anaphylaxis. He also raised the question as to whether the mucous membrane was desensitized by the injection of pollen extract under the skin when the sensitized cells lay in the mucous membrane of the upper respiratory tract.

Dr. COOKE, in closing, emphasized the fact that the subject was so new that thus far in their investigations they had only scratched the surface; furthermore, what had been done was subject to considerable revision and amendment, and certainly a much more accurate technique in every particular might be worked up.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

THE NATIONAL BOARD OF MEDICAL EXAMINERS.

Chicago, October 10-18, 1917.

(Continued from page 310)

MATERIA MEDICA AND THERAPEUTICS.

Answer the first six questions; of the remaining six choose four:

- (a) Give the source and physical properties of strychnine. (b) Describe the action of strychnine on the spinal cord.
- (a) Describe the therapeutic uses of atropine, and state the proper dose to be given in each instance. (b) Describe two therapeutic uses of caffeine, and state the proper dose to be given in each instance.
- (a) Describe the source and physical properties of morphine. (b) Explain the analgesic action of morphine. (c) Explain the constipating effect of opium.
- (a) What are the different stages of ether anes-

thesia? (b) Describe the stage of surgical anesthesia. (c) Describe the effect of hydrated chloral on the central nervous system, and give the principal therapeutic uses.

5. (a) Describe the pharmacologic action of digitalis on the heart muscle. (b) In which forms of cardiac disturbance does digitalis exert its best therapeutic effect?

6. What are the indications for the use of mercury in syphilis?

7. (a) Discuss fully the administration of quinine in malaria. (b) Write a prescription containing quinine with full directions to the patient.

8. (a) Give the source of salicylic acid. (b) Describe the effects of large doses of the salicylates. (c) Write a prescription containing sodium salicylate, with full directions to the patient.

9. Describe the pharmacologic action and therapeutic use of epinephrin.

10. Name two dissimilar drugs classed as circulatory depressants, and state in what conditions you would use each.

11. Name two evacuates acting mainly on (a) small intestine; (b) large intestine; (c) rectum. (d) Define a cholagogue, and give one example.

12. (a) Name three preparations of iron used in medicine. (b) Discuss the relative value of iron and arsenic in anemia.

BACTERIOLOGY, MEDICAL ZOOLOGY, AND IMMUNITY.

1. (a) What are the most important points differentiating streptococci from pneumococci? (b) What are our present views as to types of pneumococci, and what bearing has this on the success of serum treatment of pneumonia?

2. (a) What are the general characteristics of *B. dysenteriae*, and how do we separate Shiga strains from Flexner ones? (b) Name the anaerobic and aerobic spore bearers of pathogenic importance in man.

3. (a) Name the various organisms which may cause meningitis. (b) What are the laboratory methods of diagnosis of a tuberculous meningitis, and what are the characteristics of the spinal fluid of such a case?

4. (a) How does an antitoxic serum differ from an antimicrobial one, and give two or more examples of each? (b) What is the difference between active and passive immunity.

5. (a) What are the laboratory methods for the diagnosis of a hookworm infection, and outline the life history of the parasite? (b) How do the segments and head of *Dibothriocephalus latus* differ from those of *Tænia saginata*?

PATHOLOGY.

Answer five of the following questions:

- Discuss post-traumatic embolism.
- Contrast in parallel columns the distinguishing characteristics, gross and microscopic, of benign and malignant tumors of the breast.
- Contrast in parallel columns the distinguishing characteristics, gross and microscopic, of the lesions in internal organs, of syphilis and tuberculosis.
- Discuss the pathology of chronic interstitial hepatitis.
- State briefly the pathologic conditions which may be present ten hours after the receipt of a nonfatal perforating gunshot wound of the abdomen.
- An unknown middle-aged man has died six hours after having been found on the street, apparently in a drunken stupor: Give the general necropsy technic and the probable essential findings.
- A man 47 years of age has died two years after the onset of typical pernicious anemia: Tabulate the gross and microscopic changes probably present in the several affected organs.

ANSWERS.

MATERIA MEDICA AND THERAPEUTICS.

1. STRYCHNINE. *Source:* *Strychnos nux vomica* and *strychnos ignatia*. *Physical properties:* It occurs in crystals which are transparent and colorless, or as a white crystalline powder; it is odorless, very bitter, alkaline in reaction, almost insoluble in water, but its salts are soluble in 32 parts of water. *Action on the*

spinal cord: Strychnine "increases the reflex excitability of the spinal cord, culminating in symmetrical convulsions and tetanus. The motor reflexes are modified so that smaller stimuli are effective; and the response even to slight stimulation is maximal, tetanic, and spreads to all the muscles. There is also a reversal of inhibitory into augmentory reflexes, so that the reciprocal action of antagonistic muscles is disturbed"—(Sollmann's *Pharmacology*.)

2. **ATROPINE.** It is used (1) to dilate the pupil, render it insensitive to light, and to paralyze accommodation. The drug is applied locally, either an aqueous solution of the sulphate or an oily solution of the alkaloid being used; to avoid the toxic action a single drop of a 1 per cent. solution may be employed at a time. (2) It is also used to inhibit the secretion of sweat or saliva; small doses, such as 1/100 grain may be employed to suppress ptialism or to relieve (temporarily) the night sweats of phthisis.

CAFFEINE acts as (1) a diuretic, affecting mainly the water constituent of the urine; the solids in the urine are slightly increased. This action may be caused by cardiac stimulation, vasodilatation, or stimulation of the secretory epithelium of the kidney. Dose, 5 to 10 grains of citrated caffeine. (2) It is also used in certain forms of headache (such as migraine, neuralgia, or when due to fatigue). Dose, 7½ grains.

3. **MORPHINE.** *Source:* Opium. *Physical properties:* White or colorless prisms, or in fine needles, or a crystalline powder; odorless, bitter; almost insoluble in water, though its salts are soluble in about 15 to 20 parts of water. The analgesic effect of morphine is due to its depressing effect on the higher centers in the brain (chiefly the perceptive centers); the local action of morphine is practically nothing at all. The *constipating effects of opium* are due to the diminution of peristalsis and also of secretion; the nerve centers in the intestinal walls (Auerbach's plexus) are depressed; and there is a diminished irritability of the endings of the vagus, and also splanchnic (inhibitory) stimulation.

4. (a) The different stages of *ether anesthesia* are variously given. Thus, Hewitt classifies them as (1) analgesia, (2) light anesthesia, (3) deep anesthesia, and (4) bulbar paralysis. Sollmann's classification is into (1) the pre-anesthetic, (2) the anesthetic, and (3) the paralytic stages.

(b) The stage of *surgical anesthesia* is thus described by Sollmann: It is characterized by complete paralysis of the brain and of the motor reflex centers of the cord, and usually some depression of the medullary centers. Consciousness, sensation, and most reflexes are lost—the corneal reflex being among the last. Consequently the muscles are lax. The smooth muscles are not usually affected, but there is sometimes a relaxation of the sphincters. The pulse is full and soft, the rate slightly faster than normal; the blood-pressure is normal or rather raised. The respiration is regular and deep, often softly snoring or stertorous, and rather rapid. The temperature falls in consequence of the lessened muscular activity and increased heat loss. The pupils are somewhat small and respond sluggishly to light. The face is often cyanotic. The medullary depression does not reach a dangerous degree if the administration is carefully done. But with prolonged anesthesia, the pulse tends to become progressively weaker, the respiration more shallow, and the temperature lower—it may fall as much as 5° C. This is due to paralysis of the function of temperature-regulation.

(c) *Effect of hydrated chloral on the central nervous system:* In hypnotic doses chloral hydrate fairly rapidly induces a mild but prolonged cerebral depression, accompanied by the phenomena of natural sleep, and it is a very reliable hypnotic. The pulse and respiration are somewhat slowed, the pupil is in midcontraction, the CO₂ of the blood is reduced, as in sleep, and the patient may be fairly easily aroused by noises or pain or other sleep antagonists. From therapeutic amounts there is no essential analgesia, so that pain is not abolished, and in animal experiments it is found that there must be profound narcosis before there is any perceptible diminution in the response to painful stimuli. The reflexes are somewhat depressed, but not enough by safe amounts to make the drug more than weakly antidotal to the convulsions of eclampsia, tetanus, and strychnine

poisoning. From poisonous doses there is profound stupor, diminished excitability of the motor areas of the brain, as shown in experiments with dogs, depressed pain sense, and diminished reflexes, so that there is more or less muscular relaxation. The patient passes through stages similar to those from chloroform, and may pass to a state of surgical anesthesia (coma), with abolition of consciousness and of the reflexes, but in imminent danger of collapse. *Therapeutics:* As a hypnotic—in fever, in various forms of delirium, or in conditions of nervousness or restlessness from overwork or excesses, *e. g.*, alcoholic or sexual. It is a powerful and reliable sleep-producer in dose of 10 to 30 grains. The beginning dose should not ordinarily exceed this. As a circulatory depressant—in cases with high arterial tension, as in chronic nephritis or arteriosclerosis. Its action may be due to its effect upon the viscosity of the blood, but it is probably of very little real use. Dose 5 to 10 grains three or four times a day. In obstetrics, when the first stage is prolonged, a dose of 30 grains by mouth or rectum may give the patient rest and promote relaxation of the cervix. Chloral has some employment as a motor depressant in certain spasmodic conditions such as whooping cough, chorea, spasmodic asthma, tetanus, eclampsia, and strychnine poisoning; but for an effect in these cases larger than safe doses are required. It is of no value to check pain.—(Bastedo's *Pharmacology and Therapeutics*.)

5. **DIGITALIS.** (a) *Action on the heart muscle:* "It slows the beat of the heart; the diastole is prolonged, the force of the systole increased, and the size of the individual pulse-wave is also increased. Under digitalis the work done by the heart is much greater than normal, and the slowness developed is not sufficient to counter-balance the increased output at each ventricular contraction. Later, if enough of the drug has been taken, the heart's action becomes extremely fast and irregular, the strength of the ventricular contractions diminishes, and the output of the heart rapidly declines. Digitalis is preeminently a vaso-constrictor, and it causes a marked rise in blood-pressure; under toxic doses the pressure diminishes with the extreme slowing of the heart, but, as the organ becomes accelerated, it again rises to a pronounced degree. Finally, as the heart becomes irregular, the blood-pressure declines until it reaches zero, when the heart stops.—(Wilcox's *Materia Medica*, etc.)

(b) *Effects of digitalis in cardiac disturbance:* "The most important use of digitalis is in diseases of the heart; it is indicated, in general, when the cardiac action is rapid and feeble, with low arterial tension, and contraindicated when the cardiac action is strong and the arterial tension high. It not only slows and steadies the heart, but also improves the nutrition of its walls. It should be administered with caution, and should always be stopped as soon as symptoms of gastro-intestinal irritation occur, or the pulse becomes abnormally slow. It has a cumulative effect, and should not be given too long continuously. It is especially valuable in cases of mitral disease in which compensation has begun to fail and in which there is dropsy; when cardiac dropsy is present digitalis is usually an efficient diuretic. In diseases of the aortic valve it is of much less benefit, and is often entirely contraindicated. Still, the indication for giving or withholding digitalis is not so much the particular valvular lesion present as the effects which have been produced by this upon the cardiac wall. The constriction of the peripheral vessels caused by the drug may, when necessary, be counteracted to a considerable extent by the simultaneous administration of remedies causing vasodilatation, such as the nitrites. Digitalis is much used also in cardiac affections which are not due to valvular disease, and is highly esteemed in the weakness of the heart resulting from various acute diseases and from such causes as hemorrhage, poisoning, injury and shock.—(Wilcox's *Materia Medica*, etc.)

6. **Mercury** is indicated in all stages of syphilis, both acquired and hereditary. It has been misused and abused, but it still remains the best drug for use in syphilis.

7. (a) The specific action of quinine in malaria is due to its toxic effect upon the plasmodia causing the disorder. Quinine is most effective in the tertian, less

in the quartan and least in the pernicious malaria. It does not act equally on the parasite in all stages of its development. The sexual forms are more resistant than the usual asexual. Its strongest action is upon the forms which are just breaking into spores and upon the free-swimming organisms; it is much weaker upon the older segmenting bodies, and least upon the young endoglobular forms. Since the resistant endoglobular forms exist in the blood just before the paroxysm, and their sporulation gives rise to the characteristic chill and fever, and since quinine does not act well upon them, it will not be effectual against the oncoming paroxysm. But if it is given at this time it will be present in the blood when the spores are liberated, and as these are most susceptible to its action, it will kill them and thus prevent the development of the new cycle (providing that the dose has been sufficiently large). It should therefore be given several hours before the expected paroxysm so as to allow time for its absorption. The dose should then be quite large: 1 to 2 gm. given (fasting, if possible) two to three hours before the expected attack (which will in all probability occur), or 0.3 gm. four or five times a day in the interval; 0.5 gm. per day should be continued for three months after the last chill. To be effective, the quinine must be administered in solution. Large doses of quinine sulphate in pills or powder are probably largely wasted, since they are not dissolved or absorbed; the sulphate requires 720 parts of water for solution. The hydrochloride is more soluble (1:18) but the bisulphate (1:8.5) or the dihydrochloride is the best. It is not customary to prescribe the bisulphate directly, but to bring the sulphate into solution by the addition of a sufficient quantity of dilute sulphuric acid. The quantity of acid should be rather in excess. If it is only just sufficient, some sulphate will be precipitated on the tongue by the alkaline saliva, and give rise to a very persistent after-taste. There will be very little of this if an excess of acid is used and the mouth rinsed afterward. Urgent cases may demand intramuscular injection of quinine dihydrochloride (1 gm. in 10 c.c.) or of quinine-urea hydrochloride (2 gm. in 5 to 10 c.c.). Intravenous injections of the hydrochloride have also been used. Concentrations of 1:150 are dangerous; and even lower concentrations should be used with caution, for fear of direct cardiac effects. Ehrlich suggests using methylene blue with quinine.—(Sollmann's *Pharmacology*.)

(b) R

Quininæ hydrochloridi, 5iv.

Fluidextracti glycyrrhizæ, 3iv.

Syrupi aurantii, 5iv. M.

Sig.—Three teaspoonfuls three hours before the expected attack and one teaspoonful three or four times a day between attacks.

8. (a) Salicylic acid exists in combination in various plants, but may be obtained from the natural salicylates as the oil of wintergreen; but is generally prepared synthetically from phenol. It may also be made by combining sodium carbolate with carbon dioxide gas and then treating the disodium salicylate with hydrochloric acid.

(b) *Effects of large doses of the salicylates*: Nausea, vomiting, tinnitus aurium, deafness, vertigo, headache, mental dullness and confusion, diaphoresis, quickened pulse, deepened respiration; sometimes skin eruption, albuminuria, impaired vision, and delirium.

(c) R

Sodii salicylatis, 5iv.

Tincturæ lavandulæ compositæ, 5iij.

Glycerini, 5v.

Aquæ distillatæ, q. s. ad 5vj. M.

Sig.—Take one teaspoonful, well diluted, every three hours. If nausea or ringing in the ears is noticed, stop taking the medicine for twelve hours; and then resume the medicine, taking one-half the dose.

9. "Epinephrin excites the sympathetic nerves so as to produce a variety of effects according to the function of the part supplied by the nerve. It produces a sudden rise of blood-pressure by contraction of the arterioles. The pulse is slowed as the result of the increased blood-pressure. The heart is stimulated directly, but the resistance offered by the contraction of the blood-vessels is such that at times the heart is unable to overcome it and suffers passive dilatation.

The rise of blood-pressure which results from the action of this drug is very prompt but transient, lasting, as a rule, not more than five minutes. When given by the mouth it produces no evident effect on the circulation, but it is readily absorbed into the mucous membranes of the nose, mouth, urethra, vagina and rectum, producing local contraction of the blood-vessels. Very large doses are tolerated when given hypodermically on account of the slow absorption due to the constriction of the blood-vessels of the part into which it is injected. It acts promptly after intravenous injection, but is rapidly destroyed. Epinephrin dilates the pupil. It inhibits the peristaltic movements of the intestine and increases the secretion of saliva and other glands which receive their nerve supply from the sympathetic. It relaxes bronchial spasm. Epinephrin may produce hyperglycemia and glycosuria, and experiments on rabbits indicate that its continued use may cause a degeneration of the internal coats of the arteries. The chief therapeutic use of epinephrin is to constrict the peripheral blood-vessels by local application. A period of secondary dilatation follows. In this way it may be used to diminish hyperemia of the conjunctiva, to reduce swelling of the turbinated bones, to arrest hemorrhage from the mucosa of the upper respiratory tract, and in operation on the eye, nose, ear, etc. It is successful only in capillary or small arterial bleeding, as it cannot stop a large vessel hemorrhage. For the arrest of hemorrhage it must be applied directly to the bleeding vessels or congested area. If the blood washes it away the application may fail because it has not time to act. It may be swallowed to check hemorrhage from the stomach, but the chances of success are small because a quantity of liquid is usually present in the stomach which dilutes the remedy so that it is useless. It should not be given for internal, concealed hemorrhage, in which high blood-pressure is never desired. Epinephrin is employed in conjunction with local anesthetics, especially cocaine, to limit the absorption of the anesthetic and secure a more efficient local action. It has proved useful in relieving paroxysms of asthma both by applying a spray to the nose or throat, or by hypodermic injection."—(Useful Drugs.)

10. *Two dissimilar circulatory depressants*: Aconite, and potassium bromide.

Aconite is used in cases of high arterial tension, when the heart is hypertrophied without valvular lesion, and when with valvular lesion there is excessive compensation.

Potassium bromide is used when the heart is overacting, in cases of tachycardia or palpitation.

11. *Two evacuants acting mainly on the small intestine*: Castor oil, and jalap; *on the large intestine*: Colocynth, and sodium sulphate; *on the rectum*: Aloes, and rectal enema of soap and water.

A cholagogue is an agent which stimulates the liver and increases the flow of the bile; *example*, podophyllin.

12. (a) *Three preparations of iron used in medicine*: Ferrum reductum, ferri chloridum, and ferri carbonas saccharatus.

(b) The administration of iron in anemia and especially chlorosis often rapidly increases the amount of hemoglobin and the number of red corpuscles. It is useless in pernicious anemia; and of little value, if any, in the anemia of leukemia, exophthalmic goiter, and Hodgkin's disease. In common forms of anemia which are secondary to some special cause, such as hemorrhage, lead poisoning, malaria, scurvy, etc., the removal of the cause is essential to recovery, but the use of iron salts is often of great service in aiding the latter. . . . To restore the amount of hemoglobin and the number of red corpuscles, small doses of reduced iron or of the carbonate, or some one of the combinations with vegetable acids, are usually the most serviceable. In chlorosis better results are often obtained from combinations of iron with strychnine or arsenic than from iron alone.

Arsenic is used to some extent in the treatment of diseases of the blood as anemia, and especially in diseases of the blood-making organs which are designated as primary anemia, including leukemia, exophthalmic goiter, Hodgkin's disease, and pernicious anemia. In chlorosis as well as in instances of anemia, where iron disagrees with the patient or proves unsuccessful, it is considered a valuable agent. In these disorders the

efficiency of iron is at times much increased by the addition of arsenic.—(From Wilcox's *Pharmacology and Therapeutics*.)

BACTERIOLOGY, MEDICAL ZOOLOGY, AND IMMUNITY.

1. (a) *To differentiate streptococci from pneumococci:* (1) *Pneumococci* ferment inulin, if cultivated in inulin-serum-water medium. Acid formation from the inulin results within two days or more in coagulation of the serum and reddening of the litmus. *Streptococci* because of their inability to attack the inulin leave the medium unchanged. (2) Cultivated on whole-blood-agar, *streptococci* usually cause hemolysis, *pneumococci* usually do not. In contradistinction to *streptococcus viridans*, which does not hemolyze, *pneumococci* have a tendency on these media to form the black, dry, paint-blister colonies. (3) Normal rabbits' bile added in quantities of 0.1 c.c. to each one or two cubic centimeters of a *pneumococcus* broth culture caused lysis of the bacteria, rendering the culture fluid transparent and clear. This phenomenon does not occur with *streptococci*, and has been used to differentiate the two species. There are also differences in the agglutinations of these microorganisms in immune sera.—(From Hiss and Zinsser's *Bacteriology*.)

(b) It is believed at present that there are various types of pneumococci; two distinctive groups of pneumococci, a third group, the streptococcus or pneumococcus mucosus, and a fourth or heterogeneous group. Each of these four groups differs from the others in agglutination and serum protection experiments. The first two groups have each their own individual antiserum which may be used for treatment if used early and if it corresponds to the type of pneumococcus causing the disease.

2. (a) *Dysenteric bacilli* are small, plump, rods with rounded ends very similar to colon bacilli. They are usually single, but occasionally occur in pairs. They are not motile, and no flagella can be demonstrated. There is no spore formation. The bacillus stains readily with the ordinary aniline dyes, but is decolorized by Gram's method. The bacillus grows well on the usual culture media. Gelatin is not liquefied, nor indol produced. . . . The Flexner type differs from the others in its agglutination reaction with the patient's serum. Shiga compared the action of the immune serum on the Shiga and Kruse organism and found that they are identical from the agglutination and bactericidal standpoints. He showed that there is a difference in receptor apparatus between the bacillus of Shiga-Kruse and that of Flexner. When the immune serum is saturated with a Shiga culture, all the agglutinins and pro-agglutinoids for Kruse's organism are absorbed by the bacilli; and when they are removed with centrifugalization, the serum is no longer liable to agglutinate fresh additions of Shiga-Kruse bacilli, while its limit for the Flexner bacillus is only slightly changed or *vice versa*.—(From Shiga's article in Osler and McCrae's *Modern Medicine*.)

(b) *The spore-forming organisms of pathogenic importance to man are:* (1) *Bacillus anthracis*, which is aerobic and facultative anaerobic; (2) *Bacillus tetani*, which is anaerobic; (3) *Bacillus oedematis maligni*, which is an anaerobe; (4) *Bacillus botulinus*, which is an anaerobe; (5) *Bacillus aerogenes capsulatus*, which is an anaerobe.

3. (a) *Organisms which may cause meningitis are:* *Micrococcus intracellularis meningitidis*, *pneumococcus*, *bacillus coli*, *bacillus paratyphosus*, *bacillus pestis*, *bacillus mallei*, *bacillus tuberculosis*, *bacillus influenzae*, *bacillus diphtheriae*, *gonococcus*, and various staphylococci and streptococci.

(b) *The laboratory methods of diagnosis of tuberculous meningitis* are finding the tubercle bacilli in the cerebrospinal fluid, cultivating them from the same, and injecting rabbits or guinea pigs with the fluid or sediment, and causing tuberculosis in these animals.

The cerebrospinal fluid may be clear or turbid when drawn, but a slight deposit forms on its being allowed to stand. There is a decided increase in the lymphocytes and polynuclears in the fluid, and the tubercle bacilli may be found in the fluid or the sediment. The fluid is increased in quantity; its protein content is also increased.

4. (a) *Differences between antitoxic and antibac-*

terial sera: The antitoxic sera act directly upon the poison secreted by the living bacterial cell and neutralize its toxic property while the bacteriolytic sera affect the bacteria themselves and destroy them or paralyze their action. Since the antibacterial sera are without effect upon the formed toxin, they are mainly useful in practice as a means of protecting against bacterial invasion, while the antitoxic sera (e.g., diphtheria) may be employed to combat an infection already in progress. Broadly speaking, the latter are curative, the former protective. It must not be inferred that a given serum cannot be both antitoxic and bactericidal. If a horse be injected with a diphtheria culture containing both diphtheria bacilli and diphtheria toxin, the resulting serum will be not only antitoxic, but to some extent bacteriolytic.—(Jordan's *Bacteriology*.) *Antitoxic sera*, those of diphtheria and of tetanus. *Antibacterial sera*, those of meningitis, cholera, typhoid fever, etc.

(b) *Active immunity* is due to the direct participation of the organism concerned and depends upon increased cell activity. Such immunity is gained at the expense and often at the risk of the organism acquiring it. Immunity to smallpox may be obtained either by an attack of the disease due to natural exposure or by deliberate inoculation by vaccination with cowpox virus. This immunity depends upon a specific reaction on the part of the cells and tissues of the individual organism.

Passive immunity, on the other hand, involves no active generation of protective substances by the immunized animal. The latter is simply the recipient of substances formed in the body of another animal and transferred to the individual to be protected. When a child has been exposed to diphtheria it is the custom to inject about 1,000 units of diphtheria antitoxin into the body of the child for protective purposes. The child is then measurably assured against an attack of diphtheria, and is said to have been immunized passively, since its own tissues have in no way shared in the manufacture of the protective substance. Passive immunity may be quickly acquired, but is also much less permanent than active immunity, and tends quickly to disappear.—(Jordan's *Bacteriology*.)

5. (a) *The laboratory methods for the diagnosis of hookworm infection are:* The finding of the ova of the hookworm in the feces; and finding a condition of eosinophilia in the blood.

Life history of the hookworm.—"The ova pass out with the feces, and, under favorable conditions of warmth and moisture, develop an embryo which hatches within a few days. The resulting larvæ pass through a stage of development in warm moist earth, growing to a length of 0.5 to 0.6 mm., and moulting twice. They are then ready to infect a new host. In some cases they probably reach the host's intestine by way of the mouth, with food or water; but the usual route is probably that established by Loos. When moist earth containing the larvæ comes in contact with the skin, they penetrate into the subcutaneous tissues. This is favored by retention of mud between the toes of those who go barefooted. When the larvæ are abundant, a dermatitis is induced. From the subcutaneous tissue they pass by way of the lymph- and blood-streams to the lungs. Here they make their way into the smaller bronchi, are carried by the bronchial mucus to the pharynx, and are swallowed. They thus ultimately reach the small intestine, where they develop into mature worms."—(Todd's *Clinical Diagnosis*.)

(b) *Tænia saginata* has a head about 2 millimeters in diameter, which is square-shaped and has four suckers, but no hooklets. The segments are wider than they are long and the middle segments measure about 6 by 15 millimeters. The uterus extends along the midline of the segment and gives off about twenty branches on each side.

Dibothrioccephalus latus has an almond-shaped head with two long, deep grooves at the borders, but no sucking discs or hooklets. There are generally from 3,000 to 4,000 segments which are broader than they are long, except near the posterior end; the mature segments measure about 3 by 10 millimeters. The uterus is in the center of the segment, and is rosette-shaped and pigmented.

PATHOLOGY.

1. *Post-traumatic embolism.* "Fat embolism follows upon extensive concussion of the bony skeleton, such as may be caused by a fall from a height. So, also, after fracture of the long bones, with rupture of the fat cells of the marrow, after forcible breaking down of stiff joints, operative handling of fatty tissues, such as the omentum and panniculus adiposus, numerous capillaries of the lungs may be blocked by fat. Where only a few capillaries are involved, at most minute infarcts may be produced, with no serious results. There may be a small surrounding congestion and some migration of leucocytes; gradually the fat seems to become saponified and so removed. Its presence in great abundance may seriously obstruct the circulation through the lung, and may even produce a fatal dyspnea. The emboli may become loosened from the lung capillaries, and passing through the left heart, have been encountered in the capillaries of the heart, kidney, and brain."—(Adami's *Pathology*.)

2. "*Benign tumors* are usually very slow in growth and distinctly localized, having a definite capsule. They rarely attain excessive size, but occasionally, owing to their intrinsically benign character, may attain huge dimensions without injury to the general economy. Generally they are movable (unless bound down by surrounding inflammatory tissue or primarily attached to bone). They do not metastasize or become disseminated throughout the body, and when completely removed do not recur. They exert no influence whatever upon the general economy when favorably situated, but may endanger life by their size and situation when they interfere with the normal functions of any of the important organs of the body. They constitute the bulk of the tumors of youth, and need be removed only because of their size and location and because of the ever present danger of transformation into their correlated forms of malignant disease. *Microscopically* they can be distinguished by their non-infiltrating character, by their distinct encapsulation, by their tendency to conform to some definite type of normal adult tissue, and the absence of an actively growing edge with an abundance of cells showing karyokinetic figures.

"*Malignant tumors* exhibit diametrically opposite characteristics. They grow rapidly and usually diffusely. They are not encapsulated and may quickly attain considerable size, although huge malignant tumors are rather exceptional, since they usually prove fatal before they attain such proportions. They are intimately connected with the surrounding tissues and quickly become bound down and immovable. They metastasize and become disseminated rapidly through the lymph or vascular system, progressing steadily toward a fatal termination by the interference with vital functions caused by metastatic growths, or by an auto-intoxication which undermines the general health and produces the condition commonly known as cachexia. *Microscopically* they can be distinguished by the embryonal character of the cells constituting the growth and by their atypical structure, conforming to no definite adult normal tissue. They can be seen to be rapid in their growth by the abundance of cells undergoing indirect cell division. They are not encapsulated, but tend to invade surrounding structures, blood and lymph channels, a circumstance which explains their ready metastasis."—(Rodman's *Diseases of the Breast*.)

3. The relations of tuberculosis and syphilis are thus given by Fowler: (1) Tubercle usually affects the apex of the lung and subsequently the apex of the lower lobe and tends to progress in a certain route. The primary lesion of syphilis is often about the root and central part of the lung. The disease follows no definite line of march and gummata may be found in any position. (2) Both tuberculosis and gummata may undergo either necrosis and caseation of fibrous transformation, but with caseous tubercle the tendency toward softening and cavity formation is the rule, whereas a caseous gumma very rarely breaks down. (3) The progressive destruction of the lung by a process of disintegration leading to a gradual increase in size of a cavity, a change so commonly observed in tuberculous disease, is rarely if ever observed in syphilis, except as a secondary result of stenosis of one of the main bronchi. (4) In

nearly all cases of advanced destruction of the lung occurring in the subjects of syphilis stenosis either of the trachea or of one of the main bronchi is present, whereas this lesion is very rare indeed in tuberculosis. (5) The cavities found in cases of pulmonary syphilis are usually bronchiectatic, but not invariably so; whereas in tuberculosis they are commonly due to progressive destruction of the lung, but may be bronchiectatic. (6) The tendency to the formation of pulmonary aneurysm, which is so marked a feature in tuberculosis, is rarely observed in pulmonary syphilis. (7) Pulmonary lesions in tuberculosis are very common, whereas in syphilis they are extremely rare." Osler says that "the microscopic distinction between gumma and tubercle is always difficult and often impossible. In general, epithelioid cells are more frequent in tubercle, fibroblasts and connective tissue strands in gumma; in gumma caseation and connective tissue proliferation are simultaneous, in tubercle the latter succeeds caseation; gummatous caseation is a much slower process than tuberculous caseation; the tubercle is often free from vessels, but new-formed vessels are a prominent feature of gumma and often persist even during necrosis. Giant cells are certainly more characteristic of tubercle than of gumma."—(Osler and McCrae's *Modern Medicine*.)

4. *Chronic interstitial hepatitis* comprises the cirrhoses of the liver, the two main types of which are the portal and the biliary.

Portal cirrhosis: The size of the liver is very variable; it may be smaller than natural, and justify the term "atrophic"; in such instances it may weigh only thirty ounces. On the other hand, it may be enlarged to twice its normal size. Sometimes, but by no means always, large cirrhotic livers show extensive fatty change (*fatty cirrhosis*). The larger cirrhotic livers are less knobby or hobnailed than the smaller ones. In some instances the "hobnails" show hyperplasia, and are so exaggerated that the condition is called *nodular cirrhosis* or *cirrhosis with multiple adenoma*. A further change in the "adenomata" may result in the development of carcinoma—primary carcinoma with cirrhosis. This is a very rare event. The surface of the cirrhotic liver is irregular, granular, or hobnailed; the capsule is somewhat thickened and opaque, and may be united to the diaphragm by adhesions which are markedly vascular. The "hobnails" are lobules of liver cells squeezed into prominence by the fibrous tissue contracting around them, and are often yellow from fatty change and bile-staining, thus justifying Laennec's term "cirrhosis." As a rule the liver is uniformly affected, but sometimes the left lobe is in a more advanced state than the rest. On section the organ is much firmer than natural, and is seen to be divided up by grey, slightly gelatinous-looking strands of fibrous tissue into small compartments of varying size. Microscopically fibrous tissue in various stages of development and containing elastic fibers spreads out from the portal canals to form meshes of different sizes, and encloses a varying number of hepatic lobules. The condition is therefore called *multilobular cirrhosis*, in contrast to *unilobular cirrhosis*, where the tendency is for each lobule to be separated from its fellows by a distinct fibrous sheath. In the fibrous tissue small round cells are present when the process is advancing. Columns of deeply staining small cubical cells—the so-called new bile-ducts—are frequently seen in the fibrous tissue. Their nature has given rise to a good deal of discussion. The liver cells are atrophied, and frequently show fatty change; pigment granules are sometimes present, especially in malarial cases. Compensatory hyperplasia of the liver cells may occur, and probably plays an important part in nodular cirrhosis and in the formation of the so-called new bile ducts.

Biliary cirrhosis: The liver is uniformly and considerably enlarged and may weigh from 80 ounces to 8 pounds; except for adhesions, the surface is fairly smooth. On section the liver is firm, of a dark-green color, and granular. The large bile ducts, the gall-bladder, the portal vein, and the hepatic artery are healthy. Microscopically, each individual lobule of the liver is seen to be surrounded by delicate connective tissue (*unilobular cirrhosis*): in places the fibrillar connective tissue invades the lobules (*intercellular cirrhosis*). The connective tissue is much more fibrillar than

in portal cirrhosis, but is more intimately related to the liver cells; it contains elastic fibers, but not to the same degree as in portal cirrhosis. In most cases where the disease has existed a considerable time there is in addition portal cirrhosis; this is a secondary lesion, and is probably due to poisons manufactured in the spleen reaching the liver by the portal vein. The small bile ducts show proliferation and some fibrosis around them, while the bile capillaries often contain plugs of inspissated bile. The appearance known as new bile ducts is prominent, but has no special significance, inasmuch as it is seen in common cirrhosis, gumma, and other destructive lesions of the liver. The cells of the liver are much better preserved than in portal cirrhosis; this is correlated with the prolonged course of the disease. The spleen is much enlarged and weighs from 15 to 40 ounces, or even more, sometimes weighing more than the liver. Adhesions around it are frequently met with. (*Quain's Dictionary of Medicine.*)

5. In *non-fatal perforating gunshot wound of the abdomen*, there may be protrusion of the omentum or intestine at the external wound; if the small intestines are perforated, and the opening is small, there may be a hernia of the mucosa; hemorrhage is common in wounds of the mesenteric border of the intestine, of the omentum, and of the solid viscera; if the stomach is wounded, its contents (if fluid) will be extravasated, but the size of the wound and the condition of the stomach with regard to its contents will cause variation in this regard. "In the presence of a gunshot wound of the abdomen it is well to remember that the outcome is uncertain; the exact lesion is problematical; all penetrating and perforating wounds in the abdomen are infected; the complications that are apt to occur are uncertain; and, further, it is estimated that in all peritoneal wounds the viscera have been perforated in nearly every instance. The development of perforation peritonitis is the rule in 12 to 24 hours. The outcome will depend upon the nature of the lesion, the amount of hemorrhage, the kind of infection, and the presence of extravasation from hollow viscera."—(*La Garde.*)

6. *General necropsy technique* is thus summarized by Wadsworth (details must be sought in some standard work): (1) *Preliminary*, permit, history, identity. (2) *Exterior*, surroundings, clothing, posture, general and detail examination. (3) *Dissection*, primary cut, opening thorax and abdomen. Inspection without handling—geography. Inspection with handling—lungs, pericardium, thoracic cavity, diaphragm, peritoneum, omentum, colon, liver, intestines, spleen, retroperitoneal structures, and pelvis. (4) *Full examination*, heart, mediastinum, lungs, great vessels, esophagus, stomach, duodenum, pancreas, liver, intestines, kidneys, suprarenals, ureters, bladder, sex organs. Brain, membranes, circulation. Cord, nerves. The *probable essential findings* are: Alcoholic odor when stomach is opened; mucous membrane of stomach softened and injected, extravasation of blood in brain and membranes, edema of brain and membranes, dura may be thickened, the lungs may be congested and the heart fat and flabby, the liver may be cirrhotic and the kidneys may or may not show signs of fatty degeneration or chronic diffuse nephritis.

7. *Pernicious anemia*: "Various secondary changes are met with, those in the blood-making organs being most important. The bone marrow of the long bones is red and softened and often quite hemorrhagic. This change was formerly regarded as a primary and causal one. At the present time it is looked upon as secondary and reactive to a toxemia and, in part, to the hemolytic anemia itself. In part, at least, it represents the effort of the bone marrow to compensate for the active blood destruction. The spleen is sometimes enlarged, and may be considerably so. The liver, kidneys, and especially the heart, suffer degenerative changes (fatty) in severe cases. Similar alterations in the blood-vessels may cause punctate hemorrhages (especially in the retina), or larger hemorrhages in various situations. The lesions of the gastrointestinal tract are, some of them, doubtless secondary to the anemia; others may be primary. Degenerations of the posterior and lateral columns of the spinal cord are frequent; they seem to be due to a toxic agent rather than to hemorrhages. Pigmentation of the liver, spleen, kid-

neys, and other organs is a significant condition in evidence of the active hemolysis supposed to occur in this disease. The pigmentation of the liver is most important, and seems to be characteristic. It occurs in the hepatic cells at the periphery of the lobules and in the endothelial cells of the lymphatic channels and capillaries in the same situation. The pigment is iron-containing, and may be well demonstrated by applying the iron reactions (sulphide of ammonium; hydrochloric acid and ferrocyanide of potassium—forming Prussian blue.)"—(*Stengel and Fox's Pathology.*)

(To be continued)

Miscellany.

Shell Shock in Cows.—An interesting defence was made by a milk dealer last week in explaining why the milk sold was not of orthodox purity. The defendant claimed that the milk reached the consumer exactly as it came from the cows, but it was drawn at a time when there was an air raid and the animals were suffering from shell shock. The bench did not accept this explanation and the defendant was accordingly fined. Without discussing the defendant's statement there can be little doubt that such a defence might well be valid. It is well known that a cow through restlessness or nervousness holds back her milk, and the quality is often unfavorably affected under such circumstances. Witness the occurrence of the milk depreciating in quality when the cows are placed on exhibit. Thus the analysis of milk obtained from a cow at an agricultural show on one occasion proved to contain only 1.85 per cent. of fat, but the next day the milk was normal, containing 3.64 per cent. The quality of human milk is known also to be affected in some cases by mental strain, anxiety, or fright. Under such influences normal metabolism and nutrition may well be disturbed, with the result that the normality of the secretion of the mammary glands is interfered with. The fact calls to mind the illness sometimes produced by eating the flesh of over-hunted game or of over-driven cattle. In the big drives in the Argentine the day's journey is restricted to a certain number of miles, which if exceeded, the beasts getting tired, is apt to render the flesh unappetizing and unsound. Liebig, in his "Letters on Chemistry," published a good many years ago in our own columns, cited a case in which the flesh of a roebuck which had struggled violently after having been caught in a snare, gave rise to symptoms of poisoning, and according to Gautier pigs have been fatally poisoned through being fed upon the flesh of a horse which had died during its struggles when being broken in, and there are also recorded by the same writer cases of human poisoning by the flesh of roebucks which had died in a state of terror or exhaustion. The plea that the quality of milk can be adversely affected by shock is a quite sound one, but a valid defence would also require evidence that the shock had occurred, and that there had been no tampering with the fluid.—*The Lancet.*

War Paint.—A warning issued by the Explosives Department of the British Ministry of Munitions reveals that many English girls working in munition plants are using dangerous "war paint." T N T powder is being rubbed into their hair to impart a chestnut or auburn color.

A PLEA FOR BETTER TEAM WORK BETWEEN THE INTERNIST AND SURGEON IN THE TREATMENT OF SURGICAL AFFECTIONS OF THE BILIARY TRACT.*

By DANIEL N. EISENDRATH, A.B., M.D.
CHICAGO.

CO-OPERATION between the internist and the surgeon has resulted in more rapid advances being made in the early diagnosis and operative treatment of gastrointestinal diseases than in almost any other field of surgery. If similar team work were inaugurated in the case of lesions of the biliary tract which are amenable to surgical treatment, I feel confident that such a joint study of the causes and effects of biliary tract infection would result in earlier operations being performed in many of the

will check the disease provided that the opposite kidney is not involved and will do the work of both. Now, if the human body contained two livers, each of which possessed its own gallbladder and bile ducts and only the biliary tract of one side was infected, we should expect much better results if we removed the entire infected tract of this side rather than a portion of it. In other words, the surgeon has learned the lesson that a cholecystitis is only the local expression of a more diffuse biliary tract infection and that removal of the gallbladder alone does not cure all of the cases because both the extra and intrahepatic bile ducts and the liver parenchyma itself are infected. We cannot, as in the case of the kidney, remove the entire liver, including its excretory ducts, but must be satisfied with drainage or removal of the gallbladder combined or not with drainage of the common duct. We are confronted to-day with the problem of how to make a diagnosis and operate at a time when the biliary infection has not caused irreparable changes. The surgeon

FIG 1.—Section of gall-bladder wall showing stratified cholesterol calculi forming in the dilated crypts of Luschka (Aschoff).

cases in which the postoperative results are far from satisfactory at the present time. A relatively large experience in this field has impressed me with the fact that both the internist and general practitioner do not fully appreciate the changes which take place as the result of infection, not only in the gallbladder itself, but in the bile ducts and liver as well. It is for this reason that the internist is so often disappointed after operations on the biliary tract and places the blame upon the surgeon. In pyogenic infections of the kidney we can feel certain even before operation that removal of the involved organ

cannot be expected to do the impossible if permanent lesions are already present, and it is only by an intensive study of all phases of the subject jointly by the one who first sees the patient and the one who operates that we will make the same progress as has been made in the contiguous field of gastrointestinal surgery. This paper, then, has as its chief object a plea for an investigation by both the internist and surgeon of the causes of the relatively large number of unsatisfactory results following operations on the biliary tract. It is my intention to briefly review the most recent advances in our knowledge of the pathology and diagnosis of biliary tract infection and then to consider how

*Read at the meeting of the City Hospital Alumni Association of St. Louis, Mo., Dec. 6, 1917.

these influence the end results of operative interference, and finally how the number of cases in which there is a fatal or an unsatisfactory outcome can be lessened.

Changes in the Gallbladder.—Recent investigations of Aschoff¹, Ehrhardt², Rosenow³, MacCarty⁴, and others have shown us that there are two principal changes in the gallbladder wall which follow infection. First, there is a more or less diffuse cellular infiltration followed sooner or later, according to the number of attacks, by a thickened condition of the gallbladder wall, so that it loses its property of contractility; and second, we have changes of an ulcerative type. These ulcerations may be quite superficial and only involve isolated areas of the mucous membrane, giving rise to the so-called

bladder, the primary focus often being in the teeth, tonsils, etc. The crypts of Luschka, which are clefts lined by epithelium, extending through the wall of the gallbladder, have been found to contain organisms even after prolonged drainage of the gallbladder, and in a number of cases calculi have been observed to form in these dilated crypts. This explains many of the cases of recurrence of infection and even of re-formation of calculi after simple cholecystostomy. Another question of considerable interest and one which is being actively discussed at the present time is what the relation of an excessive amount of cholesterol in the blood bears to the formation of gallstones. There is no question but that such a hypercholesterinemia is present frequently in pregnant women, and it is a matter of common

FIG. 2.—Diagrammatic views of various forms of obstruction of common duct: *I*, large calculus found firmly impacted in ampulla of Vater with smaller ones behind it. All of these had been overlooked in this case at cholecystostomy with removal of calculi and later cholecystectomy. *II*, compression of common duct by chronic indurated head of pancreas. *III*, compression of common duct by carcinoma of head of pancreas.

“strawberry” gallbladder, or the destruction extends through the entire thickness of the gallbladder wall and is followed by secondary cicatricial contraction, converting the entire gallbladder into a rigid, greatly thinned out, inert structure, which not only has lost its power of contractility, but favors stagnation of the contents by its very rigidity. The former belief that all of the infections of the gallbladder were due to organisms migrating up the common and cystic ducts into the gallbladder must now be abandoned, because it only holds true for a small percentage of the cases. We now know that the majority of cases of cholecystitis, especially those without formation of calculi, are the result of hematogenous infections of the wall of the gall-

bladder, the primary focus often being in the teeth, tonsils, etc. The crypts of Luschka, which are clefts lined by epithelium, extending through the wall of the gallbladder, have been found to contain organisms even after prolonged drainage of the gallbladder, and in a number of cases calculi have been observed to form in these dilated crypts. This explains many of the cases of recurrence of infection and even of re-formation of calculi after simple cholecystostomy. Another question of considerable interest and one which is being actively discussed at the present time is what the relation of an excessive amount of cholesterol in the blood bears to the formation of gallstones. There is no question but that such a hypercholesterinemia is present frequently in pregnant women, and it is a matter of common

observation that gallstones are especially common in women who have borne children. Henes⁵ was one of the first to direct attention to the possibility of making a diagnosis of cholelithiasis by finding an excess in the amount of cholesterol in the blood, and other authors like Rothschild even go so far as to ascribe the re-formation of calculi to such an excess of cholesterol in the blood and speak of a cholesterol diathesis which can be controlled to a certain extent by diet. There is no question but that surgeons frequently observe a greater tendency on the part of some individuals to form gallstones than on the part of others, and from the clinical standpoint this is of great importance in cases in which both the gallbladder has been removed and

the common duct drained, for the reason that we not infrequently see a constant escape of crystalline substances, especially cholesterol, through the drainage tube, and I have had occasion to see several cases which required reoperation owing to the fact

FIG. 3.—Lymphatics of gall-bladder, bile-ducts, and pancreas (modified from Franke): 1, lymph-node at neck of gall-bladder which acts as a relay between lymphatics of gall-bladder and those of common duct. 2, lymph-node along right edge of common duct which communicates by a number of lymphatic trunks with lymph-nodes of pancreas. 3, and the last named, in turn, with interstitial lymphatics of the pancreas.

that the common duct was filled with such a crystalline detritus. In a recent paper, Gorham and Meyers⁶ have rather exploded the diagnostic value of a hypercholesterinemia, and while granting that it is a common occurrence during pregnancy, yet it is so frequently present in other diseases than cholelithiasis that it is of relatively little value as of either a diagnostic or a prognostic value. We now believe that calculi can form even when infection is not present, and this is especially true of the cholesterol stones, but as soon as infection supervenes the so-called mixed calculi are formed.

The study of the pathology of the biliary tract certainly convinces one that the finding of calculi is not absolutely essential to the diagnosis of biliary infection, and not infrequently we find only changes in the consistency of the bile, in the gallbladder wall itself, or the evidences of a more or less advanced pericholecystitis in the form of adhesions as the chief expressions of the living pathology of gall-bladder infections. I do not wish to minimize the important role which calculi play in gallbladder surgery, but I believe the time has passed when we must expect invariably to find calculi present, as a cholecystitis without calculi can cause practically the same symptoms as with calculi, but the clinical picture is not perhaps as severe a one in the former

case. From the standpoint of successful operations we must not forget that calculi play an important part, especially when they cause an obstruction of the cystic duct or of the neck of the gallbladder with retention of contents so that the virulence of the organisms concerned in the particular case is apt to have greater opportunities than if the passage toward the common duct were open. I refer particularly to those cases of hydrops, empyema or gangrene of the gallbladder wall which are among our most important indications for removal of the gallbladder at primary operations if the patient's condition and the skill of the operator permit.

The examination of our recurrence cases has plainly shown that a large percentage of those following simple cholecystostomy are due to changes in the gallbladder wall or recurrence of infection which give rise to the same symptoms as the case originally presented. That stones can re-form in such an infected gallbladder is not only possible but has been confirmed by finding them at secondary operations in which they could not possibly have been overlooked at the primary one. Even after cholecystectomy the cystic duct may dilate and form a new gallbladder. I have encountered the condition in one case clinically, and in some recent experimental work we have confirmed the observation of von Haberer, who found that the cystic duct within a few weeks becomes dilated so as to form a pseudo gallbladder.

Changes in Bile Ducts and Liver.—The effect of the presence of infection within these structures is

FIG. 4.—Calculi lying in common duct which were overlooked at previous drainage and subsequent removal of the gall-bladder. One calculus projected through and obstructed the papilla of Vater.

perhaps to-day the most important question which confronts the surgeon and is the cause of many of our unsatisfactory results. It is especially necessary for the internist to know the sequelæ of prolonged biliary infection, because the relatively high

mortality following operations on the common duct is due to the fact that the infection is so widespread throughout the liver that its parenchyma is unable to take care of the extra strain of an operation and the resulting hepatic insufficiency is the cause of many deaths which could have been avoided by earlier operation. This has been termed by some a toxemia, but the tissue changes are of more than a transitory nature, and not infrequently even the kidneys are secondarily involved and such operations are followed by an anuria which may lead to a fatal outcome. Coincident with the changes in the liver parenchyma, the infection of the intrahepatic bile passages, commonly termed cholangitis, is a most important complication. There is a great variation in the degree of cholangitis. It may be so mild in some cases as not to be recognized clinically and to be rapidly recovered from. On the other hand there are many cases in which the symptoms of cholangitis in the form of recurrent chills followed by high temperatures and profuse sweating predominate in the clinical picture. All forms of cholangitis from the very mildest to the most severe may be present in a fairly large percentage of the cases even when no stones are found either at operation or at autopsy. This is of great clinical importance because cases of cholangitis in general demand early drainage of the common duct and it should be maintained for some time as the mortality of cases of cholangitis in general, whether it is complicated by stones or not, is very high. When a cholangitis is present as a complication of stones in the common or hepatic ducts the prognosis of such cases depends in a great measure upon early drainage, and many a disappointment both as to end results in a case which had recovered, and high mortality after such operations is due to the fact that the medical adviser has waited too long before giving his consent to an operation.

We have been accustomed to teach that common and hepatic duct stones must invariably be accompanied by icterus as a pathognomonic symptom at some period in the clinical history. This observation is one which we can no longer hold as true in from 75 to 80 per cent. of the cases. Kehr found jaundice absent in 25 per cent. of his common duct cases. Bruning in 273 cases reports that in 8 per cent. there was no jaundice and 22 of 29 of the common duct cases (cholangitis) in which no calculi were found, had icterus. Van Beuren in 33 common duct cases operated at the Roosevelt Hospital found icterus absent in six, and in a recent report of 36 common duct operations by the author, icterus was absent in 20 per cent. We thus see that the internist who waits for the appearance of icterus as a symptom of hepatic or common duct calculi is apt to overlook the golden time to operate the cases in one out of every five, and the surgeon on the other hand must not be disappointed if he should operate such cases, even though icterus be present and no stones be found.

In this connection I wish to speak of the relation of the pancreas to infections of the entire biliary tract. I have called attention in another paper⁷ to the ultimate relation between the lymphatics of the gallbladder and those of the pancreas and we now believe that a large proportion of the cases of both chronic and acute pancreatitis are secondary to the

infections of the biliary tract, by way of the lymphatics. This clinical observation only confirms the necessity of early operation in cases of cholecystitis and cholangitis, both with and without calculi, before a chronic interstitial pancreatitis develops. This latter condition can by its pressure upon the lower end of the common duct simulate in every respect an obstruction of the duct by calculi. Another important observation in relation to the prognosis of gallbladder operations is that of the formation of calculi within the intrahepatic bile ducts. This has been observed in a number of cases including two of my own clinically and undoubtedly plays an important part in the recurrence of calculi after operations on the common duct.

In a recent paper⁸ I have reviewed this entire subject of recurrence after operations on the biliary passages, and the above description of the pathology of our observations, both during life and on the autopsy table, only emphasizes how important it is for both the surgeon and the internist to have a thorough understanding of these changes if we wish to have: first, more satisfactory results following our gallbladder operations; and second, to lower the mortality not only of drainage and removal of the gallbladder but of drainage of the common duct.

In closing let me hope that this paper may be of service to both the internist and surgeon in showing the former why he must not expect too much from surgical interference in cases of long standing, biliary infection and point out to the surgeon why our operations upon the biliary tract at the present day should be as thorough as is compatible with the condition of the patient. In other words, the more radical procedures should never be performed upon patients who are in a septic condition from biliary infection of long standing.

THE PROBLEM OF SYPHILIS.

BY FORREST M. HARRISON, M.D.,

ASSISTANT SURGEON, U. S. NAVY.

SYPHILIS has been definitely known to our civilization since the last half of the 15th century¹ at the time of the famous siege of Naples. The soldiers of the different countries engaged in this struggle became the victims of the disease and those of one nationality called it by the name of one of the others. The most lasting of these terms was "Morbus Gallicus," or the "French disease"; and even at this day, in the Spanish-speaking countries, it is known by the name of Gallico.

It was thought at that time to be a disease having its origin among the American Indians, and that the Spanish sailors who accompanied Columbus on his later voyages acquired it in North America, and spread it among the people of Southern Europe

on their return. There are really no authentic facts to substantiate this theory, although certain investigations were made among the graves of the mound builders in the southern parts of the United States by certain students of the subject, who found the bone lesions resembling those of the tertiary stage in abundance among the skeletons discovered in these mounds. Obscure references⁷ to ulcers and other affections are found in the early writings of the Hebrews, Greeks, and Chinese, but they cannot be interpreted as belonging to the disease in question.

This is, after all, a rather unimportant phase of the subject at hand, and it is at the most more satisfactory to the raconteur, perhaps, than to the student. Suffice it to say that whatever its origin, having reached Europe, it spread rapidly from Italy, as the best known focus, over the whole world until it has come down to us as one of the gravest problems which confronts us, not only sociologically and economically, but from a mortality standpoint as well. It is seriously occupying the minds of medical men and of intelligent and thoughtful laymen in every country of the world. On every side the subject is being discussed. Plays have been written; eugenic societies are active; charitable organizations are concerned; laws have been passed, and courses given in schools. The introduction of scientific hygiene has, to some extent, curbed its spread, but in no country within recent years has the problem been effectually and adequately grappled with.

Those of us who have much to do with the problem of syphilis cannot fail to be impressed by the fact that ignorance of the subject, despite a very voluminous bibliography, is not limited by any means to the laity. A repetition of a few sentences and statistics showing its etiology and method of transmission, together with its magnitude and prevention may, therefore, be well tolerated.

Primarily, syphilis must be considered, if we are to make any rapid strides so far as prevention is concerned, as a specific, highly contagious, constitutional disease of a slow and of a fairly typical course. The causative factor was absolutely unknown until 1905 when Schaudinn⁸ discovered a spiral-shaped organism in the serum of a secondary papule, to which he gave the name of *Treponema pallidum*. Naturally, this opened up a great field of research work which has yielded such wonderful results in the last decade. The biological and cultural characteristics of this spirillum are now so well known that it is unnecessary to discuss them here.

In the vast majority of cases the disease is transmitted by sexual congress. This is the so-called acquired syphilis which is practically always initiated by a chancre of the genital organs, the result of an infection or an abrasion or other solution of the continuity of the epithelial surface of the glans penis during coitus. It remains to be seen whether the remarkable advances in syphilography have in any way modified the much debated point as to whether or not syphilis can be contracted without the occurrence of a primary lesion. There is no doubt that many alleged cases depend wholly on imperfect observation, but it has always been known that in many infected women no port of entry can be found. Several such cases have been reported in the literature.

Following the initial lesion, there is a period of quiescence during which time the virus first extends from the lymphatics connected with the initial lesion to the first group of glands. As the primary sore is usually genital, the glands first involved are those of the inguinal region. From this point the infection extends up the main lymph channels and plexuses to all parts of the interior of the body tissues and to the periphery.

Whether syphilis is a hematogenous infection, starting at the point of inoculation and becoming generalized very rapidly throughout the tissues of the body, the chancre developing later; or whether the infection remains localized at the initial lesion for a certain time and then spreads slowly through the lymphatic channels and glands, through the thoracic duct, and finally into the subclavian vein, is not yet definitely determined. By experiments on animals, according to Neisser, it has been shown that the syphilitic virus circulates free in the blood in the very beginning. We find that the Wassermann reaction of the blood is negative during the first two or three weeks, which may mean that the specific lipotropic substances are not circulating in the blood or have not yet developed. The *Treponema pallidum* is essentially a lymph organism, but it seems probable that its generalization takes place in the early period through the blood stream, and from time to time it probably appears in the blood in the later stages of the disease.

It must be remembered that in a certain number of cases the disease not infrequently results from accidental infection. In such cases the primary lesion is usually extragenital, being located on the lips, fingers, eye, etc. This type of infection is seen in surgical and midwifery practice. Wet nurses are sometimes infected on the nipple, and it occasionally happens that relations of a syphilitic child are accidentally contaminated. An infected glass or pipe may transmit the disease and it may be carried by a third person who does not acquire the disease himself. The barber is a source of danger, and cases are reported as following razor cuts, and particularly the application of the alum stick to arrest bleeding. The stick is used over and over again and dried blood is often found upon it.

The question of hereditary transmission is also important from many angles. The transmission is most common from the father, the mother being healthy. *Treponema pallidum* has not been found in the sperm cell, but from what we know of syphilis all of the sperm cells must be infective. A syphilitic father may beget an apparently healthy child even when the disease is fresh and in full bloom. On the other hand, in many instances a man may have syphilis when young, undergo treatment, and for years present no signs of the disease, and yet his first-born may show the characteristic lesions. As a general rule, it may be stated that with judicious treatment the transmission power rarely exceeds three or four years.

In a large number of instances both parents are diseased, the one having infected the other, in which case the chances of fetal infection are greatly increased. Heredity through the mother alone is more fatal to the offspring than paternal heredity. It is a remarkable and interesting fact that a woman who has borne a syphilitic child is herself immune and cannot be infected though she may pre-

sent no signs of the disease. The mother may be infected after conception, in which case the child may be, but it is not necessarily born syphilitic. If the infection is late in pregnancy, after the seventh month, the child usually escapes.

At the present time no nation is free from the taint of syphilis, and the universal character of the scourge must be granted. Prevailing as it does on such a widespread scale, it is not only a menace to health, a handicap to progress, but a disgrace to civilization, somewhat of a slur on the skill of the medical profession, and a reflection on the intelligence of the people at large. Sir William Osler (quoted by Irvine¹) states that "Among the serious constitutional diseases, syphilis ranks next to tuberculosis, pneumonia, and cancer, from a standpoint of mortality." At first glance this seems like a startling statement, but emanating from such an authority we cannot doubt its accuracy.

An accurate statement of the amount of the disease among the various groups of our population is at the outset difficult to obtain. In regard to hospital cases, it has been shown that a large number are syphilitic, while usually entered under some other diagnosis. Thus, out of three hundred cases admitted to the Children's Hospital, Boston, Mass., Lucas² found 31 per cent. infected with lues. Churchill,³ in a hospital in Chicago, found that, of 102 children, thirty, or nearly one in three, were infected, although none were admitted for syphilis. In New York, Holt⁴ found a much smaller number, 6 per cent., among the more acute cases. Irvine¹ declares that, "In medical wards, in which patients are not admitted primarily for syphilis, 30 to 40 per cent. of all cases undergoing treatment show positive blood tests." These figures do not agree with those of Stokes,⁵ as he is of the opinion that only 6 per cent. fall within the category of the so-called accidental syphilis. Field,⁶ in a large series of miscellaneous cases, admitted to the Bellevue Hospital, found that the Wassermann reaction was positive in 25 per cent. Gerrish⁷ claims that, in 1911, 10 per cent. of the population in New York were syphilitic. In the light of these figures it seems conservative to say that there are ten million people in this country suffering from the disease. Fisher⁸ places the figure at 18 millions, while Church⁹ estimates it at 20 millions.

There seems to be comparatively little accurate information regarding the prevalence of syphilis among the insane population probably because of the fact that few asylums are doing routine Wassermanns. Ivey¹² found, among the negro insane in Alabama, 25 per cent., of 470 patients examined, positive. Mitchell,¹³ using the Wassermann test for over a year in the Warren State Hospital, found 18.5 per cent. positive among the admitted females, and 22.3 per cent. among the admitted males. Wender¹⁴ states that in 106 cases of colored male patients admitted to the Government Hospital for the Insane, for the fiscal year ending June 30, 1916, one-half were infected with lues. From these figures it is fair to assume that at least 20 per cent. of our insane in institutions are syphilitic. Syphilis was the principal cause of insanity in 19.8 per cent. of the males and 7.2 per cent. of the female patients admitted to the New York State Hospital in 1913.¹⁵ The United States Government reports for 1910

show 187,191 insane in asylums. In a former survey it was shown that the cost per capita was \$160 a year. We can, therefore, estimate that over \$30,000,000 was spent in 1910 by the States, and that \$6,000,000 went to care for syphilitics whose insanity might have been prevented. Vedder and Hough¹⁶ found, out of 616 cases examined at the Government Hospital for the Insane, 16 per cent. positive reactions. Southard¹⁷ makes the following statement: "The best information available to me as to the general percentages of syphilis is that afforded by our experience at the Psychopathic Hospital, covering 1,671 separate random tests on different persons, 14 per cent. being syphilitic."

Venereal diseases exert each year a heavy toll upon the health of the Army and Navy. In fact, Gatewood¹⁸ states that "the diseases resulting from prostitution take more of the strength of nations than all the wars and accidents." The report of Vedder¹⁹ in syphilis among recruits at Fort Slocum near New York, and at Jefferson Barracks, near St. Louis, shows that, of the entire number applying, only 17 per cent. were accepted. Among those rejected were a number who gave evidence of a history of syphilitic infection. On those recruited, Wassermann tests were performed, and it was found that 16.7 per cent. were syphilitic. Reasoner²⁰ made a survey of one regiment, showing 5 per cent. syphilitic, while Bartlett, in a year's study, found 10 per cent. of one command infected. Mudd²¹ states that, "At Schofield Barracks, during the past eight months, there have been available for continuous observation and treatment a daily average of 170 cases of syphilis." In the Navy, for the decade from 1895 to 1905, the admission ratio of syphilis was 17.5 per 1,000, and the damage figured in percentage was 7.28 per cent. In the report of the Surgeon General of the Navy for 1914, the admission rate for syphilis was 13.3; in 1915 it was 21.35, and in 1916 it was 19.83.

Such figures as these have drawn to the services an undeserved and unenviable reputation in regard to venereal disease. There are many people who believe that all the military surgeon does is to treat genito-urinary cases. It is desirable to correct this impression wherever it is possible to do so. In an ultimate analysis, an equal or even greater toll is exerted from civil life, but, owing to the interdiction which hangs over any degree of publicity on such matters, we are without adequate means of measuring it. The inexorable rule in the military services that each day of a man's time must be accounted for, and if loss of time be due to ill health it must appear in the statistical returns, has given reliable means to form an estimate of the magnitude of the scourge in the Army and Navy. There are no reliable means for making comparisons with any corresponding class in a civil community. It is evident, however, that such communities suffer much greater damage from these diseases than is generally supposed and recognized. With the system of prophylaxis now in vogue it is safe to say that a recruit is less liable to contract a venereal disease under the influence of station environment than he is under the environment of civil life.

The problem of the control and prevention of syphilis has been approached from every conceivable angle. Physicians, scientists, sociologists, and leg-

islaters of all countries have studied the question and directed their best efforts towards lessening the evil. International conferences have been held and numerous societies organized whose object has been the eradication of the great "social evil" and the consequent decrease in the enormous amount of mental, moral, and physical suffering which it leaves in its wake. Despite these facts, however, it seems to be the general opinion that preventive efforts along these lines have not met with much success. This seems strange, too, for in no disease is the sanitarian any better supplied with epidemiological information than he is in the case of syphilis. He is familiar with the germ; there is no mystery concerning its method of transmission; the remedies for its cure are efficient, and, lastly, there are efficient means of artificial prophylaxis which may be resorted to whenever exposure to infection takes place.

The only way, it seems to me, in which to attack the problem is from a therapeutic standpoint. Indeed, the most hopeful outcome of all the recent work in syphilis is the possibility of spotting the disease in the primary stage and of making an immediate and radical cure by the combination of salvarsan and mercury. Abortive treatment has been the dream of syphilographers for many years, but, so far, nearly all attempts have failed. With our present sure methods of diagnosis, however, by finding the spirochaetae and using salvarsan, the dream has at last come true, and this method of handling syphilis rests on a firm basis.

I am convinced that in early diagnosis, especially when combined with intensive and prolonged treatment, we have an effective measure for the sanitary control of this plague. That this should be so is perfectly clear, logical, and in every way obvious. It needs no explanation. The earlier a diagnosis is made, the sooner treatment may be instituted, thus healing up the open lesions quickly, making the spirochaetae less active, and rendering the chances of spreading and disseminating the infectious material from place to place and person to person very much less.

The importance of early diagnosis depends, then, on the fact that the disease, in many instances, can be aborted by early intensive treatment; but the injunction to "wait for secondaries" has been so ingrained in generations of medical men that an early recognition is not made as often as it should be. The diagnosis of syphilis in the primary stage can be established with absolute certainty, just as can the diagnosis of typhoid fever in the first week, by finding the cause of the trouble, and to-day there is no excuse for waiting until the system is thoroughly permeated with spirochaetae before giving the patient the benefit of treatment.

The initial lesion appears at varying intervals after exposure, the period of incubation being from one week to three months, with an average of twenty-one days. It is at this stage that a diagnosis can and must be made if we ever hope to make any progress in the solution of the problem at hand.

Clinically, the typical chancre begins as a minute, erythematous, painless papule, which, as it enlarges, becomes indurated, and loses its epithelial covering, appearing as a round, oval or linear erosion, whose center is covered by a grayish, glistening film, and

whose border is the color of raw muscle. Suppuration is slight or absent, the discharge being scanty, thin, and watery. Chancre is usually, but not invariably, single. When multiple, all the chancres appear at the same time, as the infection is not autoinoculable. It should be remembered, however, that a chancre does not always present the same appearance, being modified according to its situation and the presence or absence of complications which are rare. Indeed, it is generally conceded that there are three chief forms of initial lesions: a purple patch exposed by peeling epidermis without ulceration—a rare form; an indurated area under the epidermis without ulceration, a very common form, and a round, indurated, cartilaginous area with an elevated edge which ulcerates, exposing a velvety surface looking like raw ham. This is the so-called Hunterian chancre.

In this connection, it should be remembered that there are several strains of the *Treponema pallidum*. It follows, therefore, that there are many varieties of chancre. To-day, for instance, in Washington, in the laboratory of the Army Medical School, the investigators can produce several strains and varieties. They can breed a variety which will produce a chancre lacking the old Hunterian characteristics of a saucer-like indurated base, or they can produce a spirochaetae which will give a rich mucocutaneous efflorescence, or one which will be poor in cutaneous manifestations, with a tendency to confine its influence to the nervous system.

In some cases it is particularly difficult to differentiate chancre from chancroid. The latter, however, has no period of incubation, is rarely seen except on the glans penis or prepuce, commences as a pustule or ulcer, is frequently multiple, and is autoinoculable; it is usually irregular in shape, punched out and excavated, with a dirty yellowish inner base and a copious purulent discharge; if induration is present, it is softer than that of chancre, fades off gradually into the surrounding tissues, and disappears with the healing of the ulcer; it is painful, does not confer immunity against a second attack, is more frequently complicated by extensive ulceration and suppurative bubo, is healed by local measures and uninfluenced by mercurial treatment, and the bacillus of Duerrey may be found in the discharge.

Herpetic ulceration about the genitals follows fevers, neuralgia, or irritation from dirt or discharge, and has no period of incubation. It commences as a number of vesicles which may run together, forming a large, irregular ulceration, whose edges are made up of segments of circles. The discharge is purulent, but not abundant; vesicles which have not burst may be found; bubo is commonly absent, the ulceration is painful, superficial, and not indurated, but heals under local treatment.

Despite the varied manifestations of the numerous diseases which might be confused with it, a diagnosis of lues can always be made on the first day. The attempt to distinguish a syphilitic from a non-syphilitic sore by clinical appearances is in the same class with an attempt to distinguish a fracture and a sprain without the aid of the Roentgen ray. Sometimes the attempt is necessary, and often successful. As a routine measure, however,

why should we guess when we can know; and, more important still, why should we lose critical time when we can act immediately? The practice of cauterizing or powdering venereal sores before a positive diagnosis is made is worse than treating a case of fever with quinine before the malarial parasite is found, because if a sore is syphilitic the treatment not only lessens the chances of finding the spirochætæ, but has no effect on the disease. The discharge from all venereal sores should be examined microscopically, at the earliest moment, before any local treatment is used.

In former years, when our knowledge of the pathogenesis of syphilis was rather vague and limited, there was some excuse for conservatism in arriving at a definite diagnosis. In these modern times, however, with the up-to-date serological methods at our disposal, failure to suspect or even recognize a specific luetic infection in the primary stages should be considered nothing short of a crime. The demonstration of the treponemata in smears from the untreated initial lesion, either by the india-ink or by the Giemsa formula or by the dark field illumination, is comparatively easy, and involves no laborious technique. Sections cut from the chancre and stained after Levaditi's method will also show the causative organisms in great numbers, and quite recently cultural methods have been suggested.

Dark field illumination is the method of choice for examination of primary lesions on account of its rapidity and ease. A large proportion of chancres can be easily diagnosed in this way in a very few minutes. It is necessary, however, to secure a good specimen. This can best be obtained only if no antiseptic or caustic have been used for at least 24 hours. It is also necessary to use some care in taking a specimen. As the lesion is usually situated on a very sensitive part of the body, the patient may become faint and sick unless care is used to prevent unnecessary pain. The lesion should be sponged off with salt solution, and sometimes a drop of serum can be squeezed from the ulcerated area with a pair of forceps or by the patient's fingers, and can be taken up on a cover glass or in a capillary pipette. In the other cases it is necessary to puncture the indurated edge of the lesion with a broad-pointed needle, to squeeze the area, to wipe away the first drops of blood, and to continue the pressure until a drop of clear serum is obtained.

When no dark field apparatus is available the spirochætæ can be found by stained smears. A great many stains have been devised, but perhaps the most satisfactory is Giemsa's, used as follows: Serum is obtained as outlined above, spread in a thin film on a glass slide, dried in the air, fixed for one hour in methyl alcohol, and then washed and put in the staining solution for 2-24 hours. The solution consists of one drop of stain for each cc., usually 30-40 cc., of distilled water, and one drop of 1 per cent. potassium carbonate is added for each 10 cc. of water; after staining, the slides are washed off and dried in the air. The organism stains a pink to red color, and the preparation is clear, and shows well-stained cells by way of contrast.

Levaditi's stain for tissues may be of value when a suspicious lesion can be excised, but it occasionally happens that this stain will not show organisms

when they are known to be present by a previous dark field examination. In other words, the stain is not absolutely reliable, and a negative result is not nearly so conclusive as a positive one. Moreover, nearly a week is necessary for the technique.

The value of the Wassermann reaction, of course, cannot be overestimated. It is generally recognized by the profession as one of the most reliable and valuable laboratory aids that has yet been brought into use. A positive reaction means the presence somewhere in the system of living spirochætæ. The exceptions to this rule are so few, and the other diseases in which it occurs are so easy to differentiate from syphilis by the symptoms and history, that their importance may be considered negligible. Indeed, it is so nearly specific in differentiating between syphilitic and non-syphilitic conditions, that for all practical purposes one may conclude that a positive Wassermann reaction means syphilis. I have long since come to recognize in this test a splendid method of syphilitic diagnosis. At the same time, however, I have come to regard a negative reaction, in many instances, as a sore disappointment in clinching a diagnosis in which almost absolute clinical evidences of the disease are at hand. In other words, like others, I have been forced to conclude that a positive Wassermann is laboratory proof of syphilis, but that a negative Wassermann is by no means a method of proving that syphilis does not exist. The Wassermann reaction, therefore, while a boon to us in diagnosis, is at the same time in other instances a crushing disappointment.

It is almost impossible to estimate the percentage of positives that are to be found in all syphilitic cases that are daily examined throughout the medical world. Gradwohl²² estimates it in terms of 60 per cent. This is partly due to fault in the technique and partly due to a temporary or permanent disappearance of the reaction in certain persons and in certain phases of the infection, regardless of the application of specific medication. Too much dependence has been laid on the Wassermann reaction, and too many physicians rely altogether for their diagnosis on the positive or negative reports. As a result, clinical interpretations have been more or less neglected.

At the same time, serology should not be a side issue. It is too important to be anything but the main work of the physician. Frequently, with the various techniques and reagents used by different individuals, it is not at all unusual to receive different reports on the same specimen from one or two serologists. Kaplan²³ says: "I believe that the attitude of the serologist is a greater factor in the Wassermann reaction than is the standardization of the reagents. Syphilis should not be diagnosed in the laboratory, nor should the laboratory worker consider himself competent to give the final decision. The general function of the laboratory worker is not so much to detect every syphilitic, but to protect the non-luetic individual from a wrong diagnosis and useless treatment."

I am fully aware of the fact that a majority of physicians do not have the facilities at hand for carrying out the procedures mentioned in the above paragraphs. This is especially true of the general practitioner. It takes but little equipment, how-

ever, to install in an office a dark field apparatus, stains, a few slides, etc. Indeed, at the present time opportunities for arriving at a diagnosis are entirely inadequate, and unequal to the needs of the situation. In 1903, Swift²¹ published figures collected in New York in eighteen dispensaries which treat these cases. Routine examinations for spirochætæ were made in only five; only five had dark field microscopes, and only five treated cases early. Surely such a situation is indefensible on either scientific or social grounds. I believe, therefore, that the State authorities should intervene and take a hand. Syphilis is preeminently a public health question, and once it is recognized as such its eradication will be but a question of time. The establishment of municipal laboratories under the supervision of competent serologists, where tissues could be examined, Wassermann tests performed, and various other procedures for the diagnosis of syphilis carried out, would be beneficial not only to the public at large but also to the medical man himself. These examinations should be free to those who could not afford to pay for the same. A regular fee, however, charged to the patients who possess the wherewithal would be only fair, and at the same time would go a long way toward the maintenance and upkeep of the laboratory. In addition to this, the various hospitals, especially those connected with universities and schools, should have ample facilities for conducting serological and microscopical examinations, so that once a case presents itself it can be properly catalogued. Furthermore, special opportunity should be afforded to practitioners and students to attend lectures and clinics in the diagnosis of venereal diseases, especially syphilis, delivered by competent authorities.

Hand in hand with early diagnosis goes intensive, continuous, and prolonged treatment. To be effective in controlling the public dangers of syphilis it must, of course, be continued until either a cure or freedom from infection is attained. It is not within the scope of this article to discuss the different methods by which a final and complete cure will be established. They will naturally differ with the various syphilologists; whether we use salvarsan alone, or in combination with mercury and the iodides, really makes very little difference in the general scheme of things. In passing, it may be well to note that salvarsan and neosalvarsan are the most effective drugs yet discovered in the treatment of syphilis. Alone they have completely eradicated the infection in early cases before the Wassermann reaction has become positive; a large number of reinfections testify to this. Yet, even in these, mercury is recommended as an adjunct. In all other cases mercury should always be an accompaniment of salvarsan, and in many cases potassium iodide is indicated, especially in the so-called tertiary and latent cases and those involving the nervous system.

We shall leave this to the various observers to work out. We are concerned here primarily with preventing its spread, and from the purely scientific point of view we are in an excellent position to control syphilis. When a case presents itself with lesions on the surface of the body and on the mucous membranes, the first consideration in the matter of treatment and prevention is to render the patient sterile as quickly as possible, so that he will no

longer be a menace to others. In salvarsan we have a most powerful agent with which not only to accomplish this, but effect a symptomatic cure as well. It is an established fact that within a few hours after the injection of one of the arsenical preparations the spirochætæ will disappear from the lesions. To be of real and lasting value, however, such treatment must be intensive and radical. I would recommend that as soon as a case is diagnosed, whatever the stage, that the patient be given a series of three doses in a period of six days. Temporary sterilization in the dispensary or elsewhere by a single dose carries with it serious risks of neuro-recurrences, and is certainly not a substitute for the inhibitory effect that a number of injections would have.

This intensive treatment is best carried out in the hospital, for many reasons. There may be a sharp reaction following the injections, and the intervals between doses can be materially lessened. Indeed, as a contagious disease, syphilis needs hospitalization and temporary quarantine. I believe earnestly in taking the extreme medical position that syphilis should be treated in the same way as other infectious diseases, such as tuberculosis, typhoid fever, or diphtheria, by isolation, prompt and radical treatment, and by various methods of protection. If we could have a firm hand to apply well-known medical measures, we could appreciably reduce the amount of the disease. If the full force of our sanitary organizations were directed against syphilis as they would be against an invasion of cholera or plague, who can say that the disease would not be greatly restricted? To deny this is to ignore the splendid triumph of preventive medicine in other diseases.

Haphazard and incidental care mars the whole modern scheme for the effective treatment and cure of the disease. A little treatment is worse than none at all. Yet this is all the patient gets. Pillar to post truly summarizes his fate. I should like to urge, then, the possibility of the hospital, not only as a center of quarantine, but also as a center of treatment and control. Here again, however, we are confronted with lack of facilities. In 1914 it was estimated that the city of London, with a population of 9,000,000, had 163 beds actually available for the care of sexual diseases. Of 80 general hospitals in New York, a recent investigation showed that only ten received recognized cases of syphilis in the active stages. Thirteen of thirty will not even receive medical cases with known syphilis. Detroit until recently made no provisions for hospitalizing active sexual diseases, but has now developed two clinics. Chicago⁸ has the Cook County Hospital, two hundred beds to 2,000,000 people. It is estimated that one bed to 2,000 population is inadequate for the care of sexual diseases.

The State should make widespread provisions for the handling of the cases. Wherever possible, existing municipal hospitals should be utilized; if inadequate, they should be enlarged; venereal clinics should be started as a part of the general hospital, and not stigmatized by being devoted to venereal diseases alone. Such measures are more or less socialistic in their tendencies, but so are most measures for the public good, and they are justified on the ground of their importance as sanitary measures.

It is a well-known fact that at present persons affected with syphilis, in the overwhelming majority of cases, receive inadequate treatment. Indeed, the occurrence of tabes, cerebrospinal syphilis, and general paresis, is proof positive of this. Syphilographers of an earlier date and those of the present time agree that by far the most important factor in the occurrence of the late accidents of syphilis is the lack of or inefficiency of early treatment.

The question naturally arises what shall we adopt as a standard of cure. Observations over a long period of time, and repeated serological and bio-serological examinations, must be the only factors in determining the ultimate efficacy of the treatment. The treponemata may be so inactive or so locked up in the tissues that they give no symptoms, clinical or serological, for the time being. In such cases an injection of salvarsan will usually be followed in 2 to 5 days by a positive Wassermann test. This provocative injection is now recognized as essential before any case can be discharged as cured. The minimum requirement adopted by the army is "one year without treatment, no manifestations, and several Wassermann tests, none of them positive." A tentative standard of cure adopted by the army includes a negative provocative Wassermann reaction, a negative luetin test at the end of this period, and, when practicable, a negative spinal-fluid examination.

It is self-evident that in a disease so amenable to treatment as syphilis everything depends on getting all the persons affected to take treatment. With this, and only this, is it possible to restrict the spread of the plague, the enormous prevalence of which is suspected only by a few. The fact that they do not receive adequate treatment is due not so much to the fact that they do not seek medical aid as that they think they are well when the acute manifestations have subsided. Syphilitics seldom find it convenient to repeat the course of treatment necessary for a cure unless unmistakable recurrences of the manifestation drive them to the physician's door. The carrying out of adequate treatment will be impossible so long as it is optional for the heedless, the unreasonable, and the indifferent to let themselves be treated or not. I would therefore advocate in the most forceful manner legislative measures empowering the authorities to compel syphilitics to take proper and adequate treatment, and to see to it that they are kept under medical control until they are cured and no longer a menace to others.

Compulsory treatment, of course, presupposes compulsory notification. The chief objection to these measures is that it would prevent those affected from seeking the aid of a physician. It is argued that they would apply to quacks or else let the disease go untreated. That the latter would not occur is guaranteed by the pains and fear of the disease, which will be more and more effectual the more the public is enlightened on the subject of venereal diseases. Even now nearly all apply for treatment so long as there are appreciable manifestations of the disease.

The details can be worked out by the legislators. This principle of compulsory notification and treatment has proved its usefulness with other contagious diseases. It is impossible to understand why, for the sexual diseases alone, we should renounce the

principle just on account of tender solicitude for the false shame of those affected. The sexual diseases are among the worst scourges of humanity. It is our imperative duty to restrict their devastating actions on the strength of the nation. Compulsory notification and treatment are the only measures which promise effectual results, so they must be introduced, trampling down deep-rooted and otherwise justified ethical considerations. The supreme law which has facilitated so many decisions in the past must prevail here: "Health is a public question."

A discussion of the subject of prevention would be incomplete did I fail to mention artificial prophylaxis. This is practised particularly in the army and navy, and has met with considerable success. I have personally seen its efficiency in many instances. We owe this important way of combating syphilis to Metchnikoff, who proved its value experimentally. The method consists in washing the penis with soap and hot water, sponging with bichloride, 1-2000, and the application of calomel ointment 33 per cent. to the glans and shank of the organ. The shorter the interval of time elapsing since sexual intercourse the greater the certainty of escaping infection. The employment of this means of reducing the amount of syphilis has given rise to much discussion, and the question has been raised by those who regard venereal infection as a just punishment for those who have transgressed as to the justifiability of this way of prevention. It has been urged that the elimination of the danger of infection will have the effect of increasing vice. The fact that the effects of venereal disease are not confined to the individual himself, but extend to his associates, his family, and descendants, should be sufficient grounds for the use of preventive measures of this nature.

And last, but by no means least, comes the question of the education of the public; of moral prophylaxis, as it were. The mass of the people is sorely in need of systematic training and instruction in sex hygiene. We are in the midst of a reform movement at the present time. Some of the activities are admirable, and especially where medical measures are involved they are already producing results. In some quarters, however, it has been overdone and a reaction may be felt. Some enthusiasts have gone beyond the bounds of decency in their discussions of the subject. They seem to think that the naked truth has some special virtue, and, if sufficiently paraded, will automatically settle the question. I see no warrant for any such position. The deeper one goes into human nature the nearer he approaches the savage and the further he gets from morality and manners.

It is always a moot question as to what constitutes proper material to present to people in lectures, periodicals, and pamphlets devoted to a consideration of the fundamental principles of sex hygiene. We believe, of course, that the dangerous consequences of venereal infections should be neither minimized nor exaggerated. We must avoid exciting an unfavorable curiosity or giving a false sense of security, the latter being a frequent source of criticism of instruction in the methods for the use of artificial prophylaxis. It is especially an exceedingly difficult and delicate question as regards teaching hygiene in the elementary schools. I be-

lieve that a national council should be established, and recognized by the Government, as an authoritative body for the purpose of spreading knowledge and giving advice in regard to questions of venereal disease, especially syphilis, in its varied aspects.

Every effort should be made to enlighten the public as to the seriousness and the contagious danger of this disease and its distressing after effects. There should be a much franker attitude toward the venereal diseases in general. Indeed, it is not the sanitarian's armament which is to blame for the remarkable prevalence of syphilis; nor does it seem that there is any blame for indifference on the part of the individual. The fault lies hidden in the taboo that has always opposed fighting venereal disease in the open. The veil of secrecy which has spread over the subject, the zeal with which the press avoids discussion of it, and the care which is taken to keep the public from becoming acquainted with the facts in the case, have served to produce a medium in which these diseases flourish and multiply, sheltered from the sunlight of publicity, and kept at their optimum temperature for propagation by the professional secrecy with which each case is surrounded.

Let us impress upon mankind, young and old alike, the importance of selecting proper associates, and of not frequenting places where the environment is known to be questionable or vicious. Emphasis should be laid upon the remarkable prevalence of venereal diseases in general. Syphilis should be briefly described, and the public taught that it is caused by germs; that these germs obey the laws of nature as the germs of other diseases; that there is nothing mysterious about them; and that they will grow wherever they find suitable soil. Let every one know that practically all prostitutes are diseased, and that alcohol and syphilis are close allies.

In this scheme of education I believe we can appeal to the higher senses with a great deal of success. Make the young man realize that the continent life—and by a continent life I mean one in which the individual masters his impulses, and refrains from all forms of sexual indulgence—is not incompatible with good health. The impression which is so widespread that sexual intercourse is necessary to the development and maintenance of the powers of manhood should be at once corrected. Indeed, the continent life is the only rational one in relation to character. Anything which degrades the love instinct necessarily coarsens and degrades the whole of character. Right thinking, pure imagination, unselfish desires, manly conduct—these are the bricks and mortar of the character of the real man. The sensuous mind, the selfish purpose, the degrading influences which go with illicit relations, are not calculated to bring out all that is best in a man.

Then, too, an unchaste life is one of the greatest destroyers of personal efficiency. The reason is that such a life disorders the imagination. This latter is perhaps the most wonderful power peculiar to man. It may be a source of striking originality and productiveness, or it may completely sap and disorganize a man's efficiency and power. An unchaste life leads to dominance of the imagination by mental imagery of a selfishly sensual character. It weakens the will, destroys the power of applica-

tion and concentration, and dissipates high purpose.

The real test of a man's character is the way he governs his native instincts and desires and keeps them true to the ideals of his best self under unusual conditions. His primitive inclinations are the raw material out of which his character must be forged, good or bad. They may become his most loyal friends or his most relentless enemies.

Every one of us can by self-control restrain the indulgence of those imprudent and reckless impulses that so often lead men astray, and he who resists is a better man than the man of weaker will who allows his bodily appetites to rule him, and who lacks the strength of character to resist temptation and to refuse any bad example he may see before him.

Let us see to it that these great truths and principles are kept ever before the eye of the rising generation. Let us pound them relentlessly into the ears of the public whether it will or not. Then we shall have done our duty, and after we have instructed and educated the mass of the people in the ways of clean living let us put the question squarely up to the individual, and let each man consider for himself whether indulgence is really worth the price which has to be paid for it in disease, in punishment, in injury to himself, his wife, his children, in destruction of his personal efficiency, and in degradation of his own body and mind and soul. The medical profession is anxious, willing and ready to do more than its share in the teaching and treatment of this pest and scourge of the human race.

COMMON DEAFNESS; ITS MORE ACCURATE HANDLING.

BY CHARLES GLUCK, M.D.,
NEW YORK.

FROM the writer's experience in the nose and throat field during the past few years, he has come to the conclusion that the majority of cases of deafness, of either the milder or the more pronounced types, whether acute or chronic, are due to three, and in a very small percentage of cases, to four abnormalities, found in the nose and throat. These abnormalities are: *First*, and of greatest importance in most cases, are the two faucial tonsils. In all these cases the tonsils are chronically diseased, with a history of acute exacerbations at shorter or longer intervals, as a careful inquiry into the patient's history will disclose.

The *second* cause is the presence of adenoid tissue, or their remains, and adhesion bands found in the vault of the pharynx.

The *third* cause is the presence of a deflected nasal septum; this includes the presence of spurs or ridges on the septum, which are merely modifications of the deflection. This third factor is found in a large percentage, if not in all, persons suffering with deafness, and in certain cases the writer has met, he found it impossible permanently to influence the hearing beneficially, until a complete submucous operation was performed on the septum, and that in spite of the fact that proper and perfect attention was previously given to the other two cardinal factors mentioned.

The *fourth* factor is a rare one, and is found only in a small percentage of all cases and only in those persons whose deafness can be but little relieved; it consists of an inveterate and intractable disease-infected state of the anterior and posterior ethmoidal sinuses, and probably other sinuses of the nasal fossæ and cranial bones. Diseased conditions of these sinuses are really produced by the first three abnormalities mentioned, and in most cases, when not too severe, are cured by attention to these three factors, especially if the work is perfectly successful.

1. The first step, therefore, the *sine qua non* of the attempts to cure deficient hearing, as ordinarily met with in the vast majority of cases, is the complete removal of both faucial tonsils. One of the most encouraging facts met with daily in working along the lines suggested, is that the patient will feel grateful for the improved hearing to the spoken voice in a large percentage of cases in from one to a few days subsequent to the complete removal of the tonsils. This will be greatly enhanced by thoroughly clean-

ing out the vault of the pharynx, by means of both the adenoid curette and the index finger as suggested.

2. The second step is the thorough cleaning out from the vault of the pharynx of every trace of adenoid tissue present, and at the same time breaking up and removing the bands of adhesion tissue found stretching between the Eustachian tube and pharyngeal vault; this is best accomplished by the use of the adenoid curette and is immediately followed by scraping the entire vault, but especially the crevices between the Eustachian tube and the vault with the nail of the index finger (finger-scraping). This last step may be taken either at the same time the tonsils are removed or from a few days to a few weeks later. It may require repetition at stated intervals, varying from two to three months to longer periods.

3. The third step is the production of a straight and thin nasal septum. In adults this is accomplished by a complete submucous operation, and in children more or less successfully by the Ashe operation, or other means.

The removal of turbinate tissue is seldom necessary, and then only in cases wherein the inferior or middle turbinates are distinctly larger than they normally should be; and then the only work to be done on them is to reduce them to the size of normal turbinates. In operating on the turbinates it is well to remember not to remove any of the bony structure of the turbinate body, if this can possibly be avoided, during the process of reducing the turbinate to its normal size. Another point of vast importance in this connection is that all work on the turbinates should be done only from two to six weeks after the first three cardinal points mentioned have been attended to. The reason for this is, that successful attention to the aforementioned three points, *i.e.* the tonsils, the pharyngeal vault, and the septum, cures to the greatest extent the chronic nasopharyngeal catarrh from which the patient has so long been suffering; and owing to the fact that a great deal of the swelling of the turbinate bodies is due to catarrhal inflammation of its mucous membrane and substance, and that this catarrhal inflammation simultaneously disappears with the removal of the catarrhal state from other parts of the nasopharyngeal mucous membrane, the turbinates will, for this reason alone, grow smaller in size. The mucous membrane of the turbinate bodies and that of the balance of the nasal fossæ having become thinner, the nasal fossæ consequently becomes freer, "open up," as the patient says. This process, just discussed, can be materially hastened by the use, once or twice daily, of a fine nebulizing spray of 1-5000 to 1-2000 corrosive sublimate solution, applied to both nasal fossæ and throat. Thus the reason it is wrong to remove turbinate tissue, as a primary step in attempting to cure the nasopharyngeal, Eustachian tube, and middle ear catarrh, is because this catarrh cannot be cured by such removal since it is not caused by the hypertrophied turbinate tissue, as a primary and fundamental factor, but is caused in the final analysis by the three cardinal factors mentioned, *i.e.* the tonsils, the adenoid tissues and bands, and the deflected septum, and can therefore be cured radically and fundamentally only by completely removing the tonsils, thor-

oughly cleansing out the vault of the pharynx, and straightening the septum where necessary.

Another fact of supreme importance to be constantly kept in mind, when dealing with enlarged turbinate tissue is, that the complete removal of the tonsils has a greater influence in the reduction of the size of the turbinates, than any other method we may know of. The point I wish to make is the following: Frequently the turbinates will continue enlarged after a successful submucous resection of the nasal septum; bilateral nasal breathing is still found to be interfered with, the nasopharyngeal catarrh continues, and the patient is uncomfortable and dissatisfied. There is only one explanation and remedy for this, and that is the tonsils have not been removed. In fact it is best to remove them from two to six weeks preceding the submucous operation. This should be an established rule, never to be deviated from even in cases wherein the tonsils appear perfectly well and harmless. This obviates the necessity of removing much turbinate tissue, especially the entire turbinate body except in extremely rare cases. As a rule only after the tonsils and vault of the pharynx have been carefully attended to, and the nasal septum successfully operated on where necessary, may we begin to consider the removal of turbinate tissue, if necessary to reduce the turbinate bodies to the state they normally should possess, and even this should not be done until the use of a fine (1-2000) bichloride spray has been used once or twice daily on the nasal fossæ and throat two or more weeks subsequent to the successful completion of all operative work.

The removal of the tonsils has the same draining and drying effect on the nasal fossæ that a rubber drain and free opening have on an abscess cavity. In fact, the writer considers the complete removal of the tonsils the underlying and controlling key to all successful and satisfactory nasal fossa work.

The explanation of the above matter lies in this fact: Usually the patient knows and admits the need of, and comes to, the surgeon for a submucous operation; he cannot, however, understand and will not admit that his tonsils need removal. He states they have never given him any trouble, hence why should they be removed. In most cases he, however, must take this piece of advice on faith. The surgeon tells him they must be removed to obtain satisfactory nasal fossa results, *i.e.* free nasal breathing and relief from the nasopharyngeal catarrh.

In only two other instances it may be found necessary to remove turbinate tissue: (1) in cases afflicted with polyps; (2) in that type of intractable anterior and posterior ethmoidal sinusitis, wherein the three cardinal points have first been faithfully attended to and this sinusitis still persists; in such cases it may be necessary to remove the anterior tips or more of the middle turbinates in order to open up the ethmoidal sinuses. These cases, however, are made quite rare, by performing the other work as outlined. These nasty chronic types are extremely difficult to heal in some cases, except by a very successful submucous operation on the nasal septum, producing a perfectly straight and thin nasal septum, and reinforced by a perfectly complete enucleation of the tonsils, and likewise a complete removal of all adenoid tissue and adhesion

bands from the pharyngeal vault. In a very small percentage of cases even this is not sufficient, and after all the above work has been carefully and successfully done, it may be found necessary as a last resort to remove the anterior tips or even most of both the middle turbinates and open up the anterior and also probably the posterior ethmoidal sinuses in order to clean out these germ breweries. These facts will be found to be the case only in the weaker type of people, possessing poor general health.

The removal of the anterior tips or more of the middle turbinates and opening up the anterior ethmoidal sinuses, for the cure of the inevitable catarrh found in the nasopharyngeal passages of all people afflicted with acute or chronic deafness should never be done as a primary step; instead of this the work outlined above should first be done; this is the proper and rational method of cure, it will remove this so-called chronic nasopharyngeal catarrh in the vast majority of cases, if not completely, in at least from 50 to 90 per cent. of its former profuseness.

The disappearance of the swelling of the nasal fossæ mucous membrane, brought about by the removal of the catarrhal inflammation subsequent and thanks to the proper execution of the work outlined, is equally true of the mucous membrane of the Eustachian tube; the lumen of these tubes consequently becomes greater, rarefaction of the air in the middle ear, which is purely a result of interference with the size of the lumen of the Eustachian tube, does not occur so readily, and finally in many cases not at all, as the catarrhal state of the mucous membrane disappears; the middle ear is then blown out as it would be normally, as a spontaneous and automatic act, which every normal ear is capable of. Hence we see in this that the usefulness of the Eustachian catheter as an instrument in the treatment of deafness is greatly diminished, since we have so readjusted conditions that nature automatically blows out the ears. Another point based on these observations is that the writer has found that examination of the Eustachian tubes (probing) for strictures is a process seldom necessary, since in most cases a few weeks after the proper performance of the necessary work just mentioned, the tubes will be found to be patulous, and the middle ears blow out freely. For this reason the writer believes that strictures of the Eustachian tubes are of extremely infrequent occurrence. The deflected septum is injurious to the organs of hearing for two reasons: First, its deviated form shunts the air past the pharyngeal entrance of the Eustachian tube in such a manner that it assists in rarefying the middle ears; secondly, it helps to produce the diseased and catarrhal state of the nasal-fossæ structures and sinuses, thereby producing a proportionate reduction in the patient's general health. This catarrh, as explained, in conjunction with the untoward effects produced by the deflected septum, the diseased tonsils, and abnormal tissues found in the pharyngeal vault is the fundamental cause of most cases of deafness. These factors produce a catarrhal or purulent inflammatory process of the Eustachian tube and middle ear, acting to a great extent on the principle of contiguity and continuity of inflammation.

The *discharge* found in so many cases of chronic catarrhal or purulent otitis media will be greatly

diminished and practically disappear from almost all of these cases in from a few days to a few weeks subsequent to the complete tonsil removal and a thorough cleaning out of the vault of the pharynx. It may recur or not completely disappear in a small percentage of cases, but this will happen only in those affected with an acute deflection of the septum, with or without a prominent ridge, and then the desired result will sometimes not be attained until the deflection has been straightened out. These facts are equally true of cases afflicted with granulations, polypi, or both, of the middle ear. Naturally, the question of chronic mastoiditis enters here, and these cases of polypi of the middle ear, or old, nasty, chronic discharging middle-ear cases are frequently considered to be such. However, this should not frighten us, for experience teaches us that they are just as amenable to treatment along the lines suggested as the less chronic cases. The aural polyps and granulations should be thoroughly cleaned out, the three cardinal factors attended to, and we can then rest assured that neither the polyps nor the granulations will return; the chronic aural discharge will disappear very quickly—in most cases a few days subsequent to the tonsil removal. The hearing will improve more rapidly and to a greater degree than under any other means of treatment. The explanation for this is that ventilation and drainage of the middle ear and mastoid antrum and cells are established just as successfully by this internal route as they would be by the more disfiguring and graver radical mastoid operation through the external route.

Working along these lines, the writer has found it unnecessary to advise the radical mastoid operation in a single case of a large series of discharging ears of both the chronic catarrhal and chronic suppurative types. This included patients of all ages, with a history of discharging ears of both the continuous and intermittent kind, ranging from a few months to many years in duration. The length of the history did not matter as to relief from the otorrhea. The discharge would quickly disappear in all if the work was properly executed. The hearing, however, would return directly in proportion to two facts: first, the duration; and secondly, the age. The younger the patient, and the shorter the duration of the discharge, the greater would be the amount of improvement in the hearing in the shorter period of time. The older the patient, and the longer the duration of the discharge, the less could be expected as to return of hearing. Internal ear involvement, as suggested, had taken place here, however, to a greater extent; likewise, in these old cases irreparable destruction of the drum and middle-ear structures was present.

After using all agents to assist in making the otorrhea disappear more rapidly, the writer finally decided that a 1/1000 to 1/5000 bichloride of mercury solution was the best. Five drops of this instilled into the ear, after first carefully syringing with warm water and then drying with pledgets of cotton, to be used once or twice daily.

These statements, the writer has found from experience, are equally true of nearly all cases of discharging ears, as found in acute inflammatory infections of the middle ears, only the results are obtainable, as a rule, more easily, quickly and accurately.

Hence it is just as advisable to remove the tonsils and adenoids completely in cases of acute catarrhal or purulent otitis media, as soon as the patient's condition will permit this to be done, as in the chronic types. For instance, acute cases of middle-ear inflammation, requiring opening of the drum, whether in children or adults, should invariably have the vault of the pharynx thoroughly cleaned out immediately following the incision in the drum. The adenoid curette and finger should both be thoroughly used in all these cases. As soon as the pain and fever are gone the tonsils should be completely removed. Surgical attention to the septum or other nasal fossæ structures may come subsequently.

Politzerizing these acute cases as soon as the pain permits will greatly hasten the return of hearing, especially when the vault has been attended to as directed, and particularly so after the tonsils have been removed.

Judging from the truth of the above mentioned facts concerning chronic discharging ears, the method recently suggested of closing the Eustachian tube by means of producing occluding strictures in its lumen, for the purpose of relieving the chronic aural discharge, is unnecessary. This method ingrafts an abnormal state on an already existing abnormal one, whereas the steps suggested by the writer institute normal conditions, and in its final analysis is nothing more nor less than work of reconstruction, putting the parts into as normal a condition as nature herself would have them. The aural discharge disappears with more or less of a successful attempt on the part of nature to restore all parts to normal.

Regarding the *closure of drum perforations* resulting from the more accurate results obtained from the above outlined work, the writer has found that in all acute cases perforations will close with mathematical certainty in a relatively short time where a subacute or chronic mastoiditis does not remain, and will even do so in the larger percentage of these cases with an attempt on the part of nature to cure the mastoid. It is, however, a debatable question whether this should be permitted to continue, and the only solution to this problem is that each possible case of mastoid involvement is a law unto itself, and must be treated accordingly. (S. Oppenheimer.)

In chronic middle-ear cases the drum perforation will close in all persons up to about 27 years of age, and sometimes in even older people, depending on the chronicity of the case and the ability to obtain perfect results regarding the three cardinal factors mentioned. As a rule, it is in young people only, between the ages of 6 and 21 years, that great difficulty will be experienced in attempting to attain perfect results in one of the three cardinal factors, and that is in the straightening of the deflected septum, usually of the high acute type, which I have never yet failed to find present in them. In these young people it will be found impossible or difficult to close the perforation, due to the fact that the septum is deflected. One of the most difficult matters we have to contend with at present is the production of a straight and thin nasal septum in patients under 18 to 21 years of age. The aural discharge will disappear even in most of these cases under the simple but complete removal of the tonsils

and all tissues found in the vault of the pharynx; but sometimes, in a small percentage of cases, the drum perforation will not close; neither will the middle ear readjust itself to a normal state, because of the bad influence the deflected septum exerts on the ventilation and drainage, and hence the state of health of the nasal fossæ and also the Eustachian tube and the middle ear. The deflected septum shunts the air in so peculiar a manner that it rarefies the air of the Eustachian tube and middle ear, thereby interfering with the proper ventilation and drainage of the latter, leading on to disease of the middle and internal ear. It is the surgeon's duty to remedy this serious defect of the nasal septum, and it can be accomplished, though it is by far more difficult than in the adult. The facing of this difficult problem in young people is not so gloomy as at first blush it would appear to be, for the simple reason that we are dealing in these cases with young living material; and from experience we know the complete removal of the tonsils and abnormal tissues of the vault of the pharynx is nine-tenths of the battle won in most cases. It makes them safe from a standpoint of good health; it is five-eighths of the treatment leading toward a cure of the ear disease, in many cases effecting it to even a greater extent as the intervention of a few months always shows. Hence in most cases we can safely wait without anxiety, with the correction of the septal deformity, until the individual grows older.

Nerve Deafness.—From 90 to 95 per cent. of all cases of deafness, as met with daily, are due to either catarrhal or suppurative inflammation of either the acute, subacute, or chronic type, taking its origin in a diseased nasopharynx and extending into the middle and internal ears through the Eustachian tube and surrounding tissues and fundamentally dependent on the three abnormalities named. When this inflammation has invaded the vestibule and cochlea it is known under the general term of nerve deafness, this invasion occurring on the principle of inflammation of contiguity and continuity of tissues. The percentage of true nerve deafness is, however, small, and it is about as frequent as similar diseases of the optic nerve. Most cases of nerve deafness are due to disease of both the middle ear and the vestibule and cochlea, and both are due to fundamentally the same causes.

Most cases of derangements of the internal ear leading to deafness are caused by similar processes of inflammation extending from the middle ear. The internal ear is easily inflamed in this manner, most frequently by quite non-acute types of inflammation, but occasionally by acute or subacute forms. Thus deafness of the perceiving apparatus of the organ of hearing is produced. This is by far the most difficult to heal and restore to a serviceable state. These cases, however, are not so frequent by any means as cases of middle-ear disease, that is, where the disease is restricted to the middle ear only. Internal ear disease occurs, or rather let us say complicates, very acute or extremely chronic inflammatory diseases of the middle ear or improperly treated or neglected cases of middle-ear diseases, or intractable chronic catarrhal or suppurative infections of the tissues of the nasopharynx which have gone untreated, or are irremediable; for instance, old chronic abscesses of the tonsils,

acutely deflected nasal septa uncorrected, producing extremely rebellious cases of anterior and posterior ethmoidal sinusitis.

The commonest forms of deafness, therefore, are those due to inflammatory processes of the middle ear. In fact, 90 per cent. or more of the cases as met with daily are originally due to middle-ear inflammatory trouble; they may subsequently become complicated by internal ear diseases, but this is likewise due to an extension of the disease from the middle ear into the internal ear by the principles of contiguity and continuity of tissues; that is, most of the deafness is at first, for a longer or shorter period of time, due to middle-ear involvement only, but if allowed to continue too long, or in very acute cases, it will become complicated by internal ear trouble or nerve deafness.

Therefore, the next most frequent form is nerve deafness of the type consisting of disease processes in the vestibule and cochlea, structures which house the terminal nerve filaments of the auditory nerve. Diseases of these structures are due, in most cases, to similar inflammatory processes extending through contiguous and continuous structures situated between the middle and internal ears, hence such cases of nerve deafness (internal ear disturbances) are always associated with more or less middle-ear deafness (middle-ear disease), and the total deafness is the combined result of the interference with the functions of both the middle and internal ear; hence any steps that will beneficially influence the middle ear will likewise exert a benign influence on the internal ear disease, but of course not to so marked an extent, because the structures of the internal ear are by far more delicate and highly specialized than those of the middle ear, since they are actually extensions of the brain substance itself.

In fact, almost every case of middle-ear deafness which is due to inflammatory disease of the middle ear will sooner or later become complicated by internal ear deafness (by means of extension of the inflammatory process from the middle ear into the internal ear), if permitted to continue long enough; the degree of internal ear deafness will be of a milder or severer type, depending on the degree of severity and chronicity of the middle-ear disease.

Certain forms of nerve deafness are the only exceptions to this common cause of nerve deafness just described; this refers to deafness resulting from disease, injury, or disturbed function of the body of the auditory nerve itself, or of the brain centers devoted to hearing, or primary disease of the vestibule or cochlea, which should be known as pure nerve deafness. These conditions are rare when compared to the great frequency of cases of catarrhal or purulent deafness as met with daily. Pure nerve deafness is probably less frequent than optic atrophy or optic neuritis.

By nerve deafness is ordinarily meant disease or deranged function of the sound-perceiving apparatus. This is a general term, and may mean trouble located in one or more parts of the sound-perceiving apparatus, such as the vestibule, cochlea, auditory nerve, or the brain centers devoted to the function of hearing. From the pathological standpoint this can be divided into two classes: (1) Disease of the vestibule or cochlea, which is actually disease of the auditory nerve filaments or endings, and is the

most common form of nerve deafness met with; it is due to involvement of these structures by extension of similar inflammatory processes working through the middle ear; in other words, it takes its origin through the external route. (2) Disease of the auditory nerve itself, or auditory brain centers, or both, which is rare, and is caused by the disease gaining entrance through the internal or blood route.

Most cases of nerve deafness come under the first heading, and are really aggravated cases of inflammatory disease of the middle ear, which has extended into and involved the vestibule and cochlea to a lesser or greater degree by contiguity and continuity of inflammation, and has destroyed the auditory nerve filaments. These cases of nerve deafness were primarily ordinary cases of poor hearing due to catarrhal or suppurative diseases of the middle ear, and if they had been properly treated, as above suggested, at this early stage, the more serious and irremediable condition of nerve deafness would not have supervened.

Diseases causing primary permanent injury to the body of the auditory nerve or to the auditory brain centers are classified under the rarer diseases, with one exception, and that is syphilis. They take their origin internally and not externally, as do most cases of diseases of the middle ear and of the cochlea and vestibule. Syphilis is the cause of very few cases of permanent deafness through involvement of the internal auditory apparatus or central organs. This situation is comparable to primary disease of the optic nerve or other structures of the brain devoted to the function of sight, which, as we all know, are rare conditions when compared to the frequency of similar lesions produced by other causes.

The diseases injuring these aforementioned central structures are brain diseases; for instance, in the fetus, congenital brain diseases leading to lack of development in the structures devoted to the function of hearing; they may be of a syphilitic nature or other infectious type; in the infant or child they may be such diseases as cerebrospinal meningitis, anterior poliomyelitis, or other rare and insidious diseases of this nature. In the writer's experience, he is thankful to say, he finds these conditions occupy a small percentage of all cases of deafness. The diseases that commonly destroy the hearing are produced by the common ordinary infectious type of germs encountered daily, and which get into the structures of the hearing apparatus *not* through the internal or blood route, but by means of the external route—through the nose and throat—and they do this only by the assistance rendered them by the three, or sometimes four, abnormal structures mentioned; these three or four factors are the levers which the disease germs use to break into the structures of the hearing apparatus and destroy them; hence, if we remove these three or four abnormalities we can very frequently prevent deafness, which would of necessity come on either early in the individual's career or as he grows older. If deafness is already present, the patient will obtain relief to a greater or lesser extent, or even complete cure, all depending on how much destruction of the hearing apparatus has already taken place.

Hence, deafness is caused most frequently by invasion through the external route, and this includes most cases of deafness due to destruction of the internal or third division of the auditory apparatus (nerve deafness), particularly restricting ourselves to the structures composing the vestibule and cochlea. Since pathologically and clinically it can easily be proved that either acute, subacute, or chronic inflammatory processes of the internal auditory apparatus are produced by the spreading of similar processes from the middle ear through the foramen ovale and foramen rotundum and the other contiguous tissues, both bony and soft, which make up the structures situated between the middle and internal ears, and this by the well-established principles of inflammation of contiguity and continuity of tissues.

Without a doubt it is an extremely difficult matter to improve a patient's hearing whose deafness is due to a diseased state of the structures of the internal ear. But, as shown above, most of these cases of disease of the internal auditory apparatus are due to extension from the middle ear, and if the middle ear is benefited by the above work, and the hearing thereby improved, it will be observed to be true that in practically all cases of deafness due to disease of the internal auditory apparatus produced as explained above, there is also, after a longer interval of time, a small amount of improvement in the hearing; and what is of more importance, the patient does not continue to grow steadily deafer and deafer until the stage of absolute deafness is reached. Therefore it is only logical and fair to remove the causes, if we are positive that those are the causes underlying the whole trouble and producing the disease in both the middle and internal divisions of the auditory apparatus. This should be done even though it is rather late in the stage of the disease, since a little improvement is better than none at all. Our indications for operating are the usual ones. Age is only a factor from the standpoint of the patient's willingness or ability to stand the strain. The younger the better. Those less than forty are preferable. Well-selected cases well past forty should not deter us. The writer has grown so optimistic that he has done the work, in well-selected cases, even in patients well advanced in the middle span of life.

Furthermore, the writer believes that this work has the greatest tonic effect on the patient's system he can possibly obtain, as an interval of six months to two years after the operative work has been completed will show. The individual's health in general is vastly benefited, colds and infectious diseases become less and less frequent, and the resistance continues to increase steadily. It is all work of reconstruction, attempting to make the patient's nasopharynx as nature herself would have it; the patient receives his air in normal quantities and in a properly prepared form, so the oxygen can be assimilated by the lung tissues in normal quantities; oxygen, as we all know, is by far more important than food. This normal state of the nasopharynx reflects itself on the patient's system generally, making him as normal as can be, providing too much destruction in other systems has not already taken place.

Work of this type should, of course, be preceded

by general and special thorough scientific and painstaking examinations and investigations. In this connection the various tests for hearing, such as the Schwabach, Rinne, acumeter, whistle, spoken and whispered voice, etc., should all be carefully recorded at the proper intervals. The watch tick is extremely satisfactory for use in one's daily work; it is second to none in obtaining quick and accurate information during the general progress of the case, especially in younger people, who are affected mostly with middle-ear disease. It will divulge a world of information in a few moments. One must be careful in using it, and the eyes should be shut, so as to avoid innocent self-deception. The Schwabach and Rinne tests are, of course, our best means for distinguishing between internal and middle-ear lesions, or recognizing a combination of the two, as most old cases will disclose; the watch tick can be used for quick, accurate determination of the improvement in middle-ear cases, which are the more recent cases, and which are found mostly in younger subjects.

Regarding the tests for deficient hearing, we must remember that their principal value rests on their ability to distinguish between middle and internal ear disease. But after looking at it as pictured above, we must come to the conclusion that it is scarcely necessary to lay too much stress on their importance in this respect, for the simple reason that internal ear deafness is merely an extension of middle-ear disease in most cases. Hence, in most cases where we find internal ear trouble we shall find middle-ear disease, and in a large percentage of middle-ear cases that have stood long enough, or have been sufficiently acute or chronic, there will be found more or less involvement of the internal ear.

A word as to one of the most annoying symptoms invariably found in people growing deaf, and that is the tinnitus. I know of no treatment which will exert as beneficial an effect on the tinnitus as that suggested. The patients will all admit, some after rather short intervals subsequent to the completion of all the work, others after two or more years, that the sounds are milder, less annoying, and not quite so loud; and many lay their improvement in hearing to the fact that the sounds are not so loud or annoying, and heard less frequently.

Summary.—Most deafness is due to from two to four abnormalities to be found in the nasopharynx; this is true of both middle-ear and internal-ear (nerve) deafness. They are all capable of relief to a greater or less extent, and frequently can be completely cured by the methods suggested above; middle-ear cases from a few weeks to longer periods, middle and internal ear cases requiring two or three years before satisfactory results appear.

2626 BROADWAY.

Dysenteric Rheumatism.—Dorendorf has seen 59 cases of this affection which he also speaks of as a "rheumatoid." It is essentially a phenomenon of convalescence and is more prone to attack the rheumatic than the hitherto normal subject. A bacterial cause or infectious nature has not yet been shown to exist. The affection does not yield to antirheumatics or to specific antisera. It is very obstinate toward treatment but will end in recovery with time.—*Correspondenz-Blatt für Schweizer Aerzte.*

A NATIONAL BUREAU FOR THE WAR CRIPPLES OF FRANCE.

By DOUGLAS C. McMURTRIE,

NEW YORK.

DIRECTOR, RED CROSS INSTITUTE FOR CRIPPLED AND DISABLED MEN; PRESIDENT, FEDERATION OF ASSOCIATIONS FOR CRIPPLES; EDITOR, AMERICAN JOURNAL OF CARE FOR CRIPPLES.

DURING the first year and a half of the war the efforts of the French government in behalf of disabled soldiers were directed by at least four different ministries. The Ministry of the Interior was engaged in the work because the extension of aid to discharged soldiers was within the scope of the *Bureau d'assistance publique*; the Minister of War had a part in it because soldiers still in military hospitals were under his jurisdiction; the Minister of Commerce, because the supervision of technical instruction was one of his functions; the Minister of Labor, because the placement of men in industry was obviously a labor question. This dispersion of efforts resulted inevitably in overlapping or conflicting activities, in confusion, and in waste. To prevent the continuance of these conditions it was clearly necessary to combine the activities of the different ministries in reference to disabled soldiers into some central co-ordinating department.

Accordingly, in March, 1916, the *Office National des Mutilés et Réformés de la Guerre* was created by inter-ministerial decrees, with the expressed object of coordinating the work of the ministries and of public and private institutions dealing with the *mutilés*, and of centralizing all useful information on the subject. Headquarters of the *Office* are at 95 quai d'Orsay, Paris, and sub-offices or committees have been formed in nearly every department in France. The work of the main office is divided among a committee of administration, a committee of re-education, and a committee for looking after the general interests of the *mutilés*.

One of the first tasks undertaken by the administration committee was to keep a registry of every invalided soldier. To this end it prepared a blank on which could be indicated a man's residence, his dependents, his civil or military status, his schooling, the nature of his disability, his former occupation, the re-education that he had received, and what kind of employment he desired. This blank is filled out by the medical service for every man in hospital before he leaves; to it is attached a card of "medical observation" describing his prosthesis if he has one, his functional capacity, and his aptitude for vocational re-education, and both cards are then sent back to the *Office National*. When a man finds employment a placement card describing his situation completes the record.

Along with this registry work the committee went into the question of possible occupations for variously disabled men, and by means of extensive inquiries among manufacturers was able to draw up tables showing on the one hand the occupations open to men with all the different kinds of disabilities, and on the other the disabilities compatible with different occupations. Cases of victims of industrial accidents who were earning a good living were brought to light by this investigation and are made to serve as encouraging examples to the victims of the war. At the same time the manufacturers were informed of ways in which they might help to in-

crease the country's available labor supply. It was suggested that they might reserve certain places for soldiers, make changes in their machinery to adapt it to the disabled, or equip workshops for apprentices.

The re-education committee of the *Office National* is occupied with the organization and control of schools for vocational re-education. It recognizes four types of institutions found in so-called "centers" of re-education; the school with attached workshops, conducted solely for disabled men, the boarding-house which supplies maintenance to men serving as apprentices in private shops or attending regular technical courses, the guild schools opened to disabled men by the trade unions, and the system of providing maintenance to men living at home on condition that they pursue a faithful apprenticeship in some trade. The *Office* further classifies re-education schools by their financial and administrative control. Thus there is one, the *Institut* at Saint-Maurice, founded by the national government, which is under the direct control of the Minister of the Interior; others are under the authority of a department, municipality, or chamber of commerce; and still others are wholly in private hands. Schools of the latter two classes receive a subvention from the Ministry of the Interior on the submission of their program of instruction, their regulations, and a statement showing their resources and probable expenses. It is the task of the re-education committee to investigate schools applying for or receiving a subvention and to advise the Ministry of the Interior.

In order to obtain precise information about the work of the various schools and the state of vocational re-education in France, to know whether new schools should be started or whether a certain kind of instruction should be developed at the expense of another, the *Office National* sends out about twice in the year a questionnaire by which it collects many valuable statistics. Each school is asked to furnish information on the number of its boarding and day pupils, the composition of its teaching force, the machinery and tools at its disposal, its financial situation, the trades taught, the number of disabled men re-educated during the last six months, the number of days of attendance, and the list of men placed in positions on the completion of their course, with a note indicating whether they were placed in their former trade or a new one. The questionnaires answered during 1916 disclosed the small number of disabled soldiers undergoing re-education compared with the number of those incapacitated for their former trade, and indicated the necessity of propaganda to induce men to enter the schools. For this purpose the *Office* drew up and posted in all hospitals and public places a notice informing wounded soldiers that the state wished to aid them not only with a pension but with the means of learning a trade, and including directions for taking advantage of the opportunity. The notice of course stated decisively that the amount of the pension would be in no way diminished by the recipient's increased earning capacity. As a result of this advertisement the *Office* has received a large number of requests for further information from men interested in a means of obtaining trade training.

In the matter of placement the role of the *Office National* is, again, to coordinate the work being done by existing bodies. On the basis of reports transmitted to it by the various institutions occupied with placing disabled soldiers, it publishes every month an "Employment Bulletin," containing a record of all the placements made throughout the country with a description of the disabilities of the men placed, a list of the positions that have not been filled, and a list of the demands for employment that have not been satisfied. By means of this Bulletin every employment bureau can know what the others are accomplishing, and demands that cannot be met by one can be passed to others.

An even closer coordination has been effected among the employment bureaus of Paris. For them a bulletin is issued every day, and is distributed to all the bureaus participating in the service before two o'clock every afternoon. It contains a list of the offers of employment which have not been met by the bureaus where they were received, a list of the positions published as open in preceding bulletins, which have since been filled, and a list of those to which candidates have been sent and which are possibly no longer vacant. Any office receiving the bulletin has, therefore, at its disposal for the benefit of the men it wishes to place all the offers of positions recorded in the different employment bureaus of Paris.

In looking after the general interests of the *mutilés*, the committee in charge attempts to coordinate the work being done by the different aid societies and to avoid the abuses which often accompany charitable giving. Its efforts are ably seconded by the "Departmental Committees," whose chief mission is to see that every disabled man of the department receives the guidance and aid he needs. The Departmental Committee is also a coordinating agency for the various societies and institutions dealing with the *mutilés* in the department; it oversees their activities, and when necessary initiates new organizations. It is usually composed of the Prefect as president, of men representing the government—the different ministries, the medical service, the departments of public and technical instruction—and of members of the medical profession, employers' associations, insurance societies, trade unions, and rural credit banks. The duties of the Departmental Committees, as determined by the *Office National*, include visits to the men in hospitals with the object of influencing them toward re-education, investigation of industries, and advice about choosing a new trade, maintenance of close relations with the re-education school if none exists to serve the needs of the department, collaboration with the departmental employment bureaus, investigation of all offers of positions with reference to their permanence, wages, and neighboring living conditions, help in the enforcement of the law which reserves certain positions to disabled men, examination of artificial limbs distributed to men in the department and the encouragement of new inventions and improvements, publishing information on laws from which the *mutilés* may benefit—concerning insurance, workmen's compensation, rural credits, and the like—and watching helpfully over their future welfare after they are settled in industry.

THE NEED FOR AN INTENSIVE STUDY OF THE MORTALITY ASSOCIATED WITH CHILDBEARING.*

By GEO. W. KOSMAK, M.D., F.A.C.S.,
NEW YORK.

ATTENDING SURGEON, LYING-IN HOSPITAL.

CONTEMPORANEOUSLY with the wastage of human life that is now going on in the world war, perhaps the greatest in all history, we meet with numerous expressions directed to the necessity for replenishing the resultant shortages in population, for each affected nation recognizes the fact that unless its birth rate exceeds the death rate it must succumb in the struggle for national existence. Even a life half extinguished in the mortal conflict that has now involved the greater portion of the surface of the habitable globe, is sought to be restored to some degree of usefulness and the maimed, the crippled, and the blind are being reeducated by elaborately devised measures to resume their functions, in part at least, in the economic life of their respective countries. And so in civil as in military medicine the triumphs of recent generations are centered in the efforts to reduce the mortality from diseases that may be prevented or if not entirely preventable, at least to reduce the number of their victims. No greater honor attaches to medicine of the past century than the recognition of the fact that typhoid, diphtheria, tuberculosis, smallpox, and numerous other diseases are in a large measure preventable and, if these become a scourge, it is largely due to the circumstances that human neglect has in great part entered as a factor in their spread. So, likewise, the wastage of infant life has been made an object of preventive medicine with results so well known that they need not be referred to here.

But the attention directed to the reduction of infant mortality has conclusively demonstrated the necessity for a more complete supervision of the mother, both before and after labor, and as a result of this study, facts have been uncovered with reference to the mortality of childbearing that demand our best efforts for their recognition and possible correction. It is now well known and admitted that in this country no such decrease in the number of deaths associated with pregnancy has occurred as compared with those due to other causes; for while in the United States the death rate for typhoid fever between 1890 and 1913 fell from 46.3 to 17.9 per 100,000 of the population, for diphtheria from 97.8 to 1.8, for tuberculosis from 252 to 147.6, for pneumonia from 186.9 to 132.4, the total mortality associated with childbearing has not undergone any corresponding change for the better. Thus, in 1891 the total mortality associated with the childbearing function was 15.3 and showed little variation up to 1913, when it was 15.8 in the same ratio of population. These rates refer to the so-called registration area, which in 1913 included between 65 and 70 per cent. of the total population of the United States. A further study of the mortality tables presented in the last national census shows that the death rate per 100,000 women of childbearing age in 1900 totaled 50.3 and included 21.6 for puerperal sepsis alone. These figures may, perhaps, be criticised for lack of sufficient detail and

a more accurate estimate would be one based on the number of deaths of mothers per 1000 live births. This has only been done in a very few States, but even here we note a rate of 6.5 per 1000, or in larger figures and round numbers, about 3,600 out of 562,000 pregnancies with live births had a fatal termination. Here, again, we find that in about one-half of this number puerperal septicemia in some form or other was shown to be the cause of death. Attention has also been called to the fact that among the sixteen leading nations of the world an examination of the death rate associated with pregnancy shows that the United States stands fourteenth on the list.

If we admit the facts as stated what can be done to correct the same? I believe that in the first place an attempt should be made to disseminate a more widespread knowledge of the comparatively high mortality associated with the function of childbearing, so that the medical profession and the public, as well, shall be made aware of the necessity for concerted action and take steps to attain the same. Secondly, the preventable character of many of the fatal complications of pregnancy should be emphasized and due recognition accorded to the necessity for providing skillful attention for every pregnant woman. Thirdly, it seems essential that a more detailed study be made of the mortality statistics of pregnancy and labor, in order to determine among other things the antecedent history of the fatal cases and to separate in greater detail the various causes of death, for, at the present time, the usual classification includes merely septicemia on the one hand and the remaining factors on the other. This is extremely unsatisfactory, for it gives us little idea of the direction in which to apply prophylaxis, either in a medical or social sense.

The intensive study of the subject herewith proposed is based on the mortality associated with childbearing in hospitals of the Borough of Manhattan of this city during the half decade from 1913 to 1917, inclusive. Only those deaths which occurred in the hospitals of this borough are included, as this for obvious reasons, probably represents the more serious phases of the situation. In the belief that the hospital records are necessarily more complete than those derived from private practice, deductions may be possible, which could not be obtained otherwise. Moreover, a study of the hospital statistics will show how many cases originated in the institutions or were referred to the same from outside sources, and in this way an idea may be gained as to what proportion of fatal cases might perhaps have been saved with earlier and, let us say, more skillful treatment. The care of a woman in labor has usually been considered as coming within the province of the general practitioner to be conducted at home under conditions that even under the most favorable circumstances can scarcely be described, in many instances at least, as meeting the demands of aseptic surgery. The poor and the well-to-do can command the services of competent obstetricians, but the great middle class must still depend on what may be charitably termed "average ability or talent", and it is along these lines that the campaign of education for better obstetrics must be conducted. If the detailed mortality statistics of a great metropolitan center can be gathered and classified, their publication will un-

*Read at a meeting of the New York Obstetrical Society, Feb. 12, 1918.

doubtedly lead to similar efforts elsewhere, and a problem that now appears vast will assume limits that permit of closer study. Hospital statistics afford material for analysis that will be productive of greater certainty and more satisfactory deductions than that secured from the official death certificates on file at the Board of Health, as the latter failed to give the very much desired information about the antecedents of the individual case. Where hospital records are faulty in this respect, it is to be hoped that such publication will lead to reform in their future preparation.

The Public Health Committee of the New York Academy of Medicine, in a most public-spirited manner, has undertaken this investigation. From it we ought to obtain certain definite information of the proportion of the various etiological factors that have contributed to the mortality of pregnancy and labor, to know of what value prenatal work has been, whether previous neglect of the attendant before referring the particular case to the hospital is a factor in the situation, how many operative deliveries ended in fatalities, and what are some of the underlying conditions in the production of puerperal septicemia. For this purpose, a questionnaire has been prepared as affording the most satisfactory and easiest way to collect these statistics, which it is our intention to assort and arrange without reference to the hospital from which they are derived. The purpose is not to criticise any individual institution, but to present a set of collective statistics that will serve as a basis for a constructive reform in reducing childbirth mortality, if this is possible. We trust that the work will be accepted in this spirit by the profession, and we are glad to acknowledge the practically complete cooperation of all the hospital authorities who have been appealed to for their assistance. The New York Obstetrical Society has likewise given its indorsement to this important investigation. It is hoped that within six months these statistics will be available and ready for publication.

23 EAST NINETY-THIRD STREET.

STANDARDS FOR SWIMMING POOL LEGISLATION.*

By WALLACE A. MANHEIMER, PH.D.,

NEW YORK.

SECRETARY AMERICAN ASSOCIATION FOR PROMOTING HYGIENE
AND PUBLIC BATHS.

THE writer has been consulted a number of times by the health authorities of various communities concerning the requirements of public health ordinances relating to swimming pools and bathing beaches. The widespread interest which has been shown in the proper safeguarding of swimming pools has prompted the brief detailing of the standards up to which the laws enacted should measure. While it is recognized that the requirements of different localities may make the modification of the standards below suggested a necessity, neverthe-

*The present paper was compiled through the facilities of the Research Laboratory of the New York Department of Health. Many valuable suggestions have been made by Dr. Haven Emerson, former Commissioner of Health, and by Dr. William H. Park, Director of Laboratories, to both of whom thanks are herewith given.

less, in the main, the problem of pool sanitation is the same in all communities.

Swimming pools may be classified as indoor and outdoor pools, fresh and salt water pools, wading pools, and mikveh baths. The regulations concerning mikvehs have been published in a previous issue. For details concerning outdoor bathing beaches, consult the laws of the State and City of New York.

The regulations concerning pools can be conveniently divided as follows: (1) Regulations concerning the management of the water; (2) regulations concerning the construction of pools, including the reduction of fire hazard and the provision of safety devices; (3) sanitary control of premises and bathers. No attempt is here made to set forth the regulations, merely standards are suggested.

A. *Standards Concerning the Management of the Water.*

1. The bacterial contents of the water supplied to a swimming pool must conform with that of drinking water, or, if polluted, must be disinfected before use.

2. The water in the swimming pool during use must be continuously diluted by adding fresh water, or, by re-using the water from the swimming pool after filtration. (Note: It is preferable to keep re-using the pool water by a process of circulating it through a filter—refiltration. This will conserve both the water and the fuel for heating.)

3. The water must be maintained clear at all times to an extent at least sufficient to see a submerged person in any part of the pool. (Note: The manner of accomplishing this should be left to the proprietor of the establishment; however, the most satisfactory method so far introduced is by the continuous circulation of the water through a filter—refiltration.)

4. The water must be either periodically and regularly or continuously disinfected, unless emptied daily. The bacterial count must not exceed 10 colon bacilli per cubic centimeter. (Note: No upper limit for total bacterial count should be set until further experience has been accumulated on pool sanitation. The frequent emptying of the pool should not be compelled or encouraged because disinfection and refiltration give as good results as frequent change of water and because the frequent change of water causes needless waste of water, fuel, power for pumping, etc.)

5. The method of disinfection must be satisfactory to the Department of Health. (Note: No method should be prescribed in view of the advances constantly being made on this phase of pool sanitation; chlorine and other chemicals, ultraviolet light, and particularly ozone, all have their advantages.)

6. The water from the pool must, when discharged, cause no contamination of any stream used for drinking purposes and should, if possible, be disposed of as sewage water.

B. *Standards Concerning the Construction of Pools, etc.*

1. The lining of the pool must be white or nearly so, smooth (readily cleansable), and impervious to water. The corners of the pool should be rounded.

2. There must be no obstructions in the water. Stair and stair supports must be of metal or stone.

3. Water from the floor surrounding the pool must not drain back into the pool.

4. The floor must be constructed of material impervious to water, must be adequately drained and composed of material designed to prevent slipping, and, if possible, a poor conductor of heat.

5. There must be a scum gutter on at least two opposite sides of the pool, and preferably completely surrounding the pool, for the purpose of draining off surface dirt and of affording a place for bathers to spit. The scum gutter must drain into the sewer or cesspool and not back into the recirculation system.

6. Construction should be made with due regard to the elimination of fire hazards, taking into account the providing of sufficient exits to accommodate the largest crowd that would be likely to attend exhibitions, etc.

7. The pool should be shallow at one end and deep enough at the other to permit diving with safety, unless constructed as a wading pool for children.

8. Dressing room compartments in indoor pools must be constructed vermin-proof.

9. Bathing establishments should be under permit of the Department of Health to include construction and operation.

10. Adequate shower baths and toilet facilities must be provided; also hot water for showers in indoor pools; toilets must be screened against flies, unless water-flushed and covered by toilet seats.

11. Sanitary drinking fountains with pure water must be supplied.

C. Sanitary Control of Premises and Bathers, etc.

1. Adequate light and ventilation must be provided.

2. A temperature of the air during the winter in indoor pools of between 70 deg. and 80 deg. F. must be maintained.

3. No common towels, combs, brushes, or drinking cups may be provided.

4. All towels, suits, etc., provided by the establishment for public use must be sterilized after each separate use.

5. Anti-spit signs must be conspicuously posted. Signs in large letters must be posted in dressing compartments directing all bathers, men and women, to take a preliminary cleansing shower in the nude with warm water and soap and to empty the bladder before going into the pool. All bathers must rinse off the soap before entering the pool room.

6. No diseased or intoxicated person should be permitted to use a swimming pool.

7. Only persons dressed for bathing may enter the pool room.

8. Men and boys must bathe in the nude or be provided with sterilized suits. Suits for men and women must be of fast color and of a lintless material.

9. A life guard must be present at all times. He must be acquainted with the technique of resuscitation of the apparently drowned and have equipment at hand for rescuing and resuscitation. He, or some attendant, must supervise the incoming bathers to enforce the regulation concerning the preliminary bath and to exclude undesirable and diseased persons.

10. The room must be locked during the emptying and refilling of the pool, or other steps be taken, so

that bathers will not accidentally dive into an empty pool.

10. The pool when emptied must be well scrubbed,

12. No smoking should be allowed in indoor pools,

13. Cuspidors must be provided in the dressing rooms and pool rooms.

14. If the tub baths are supplied they must be disinfected after each separate use.

Medicolegal Notes.

Physician's Representations Leading to Release.—In a passenger's action for injuries, to avoid a release the plaintiff pleaded false and fraudulent representations by the defendant's claim agents and its physicians as to her physical condition. It was held that the burden of proof rested on her to prove that the doctors and the claim adjusters deliberately and consciously misrepresented her physical condition, with intent to induce her to make the settlement, and that she was thereby induced to make it. To prove fraud the evidence must be clear, precise and indubitable. It was held that such evidence had not been presented. The plaintiff herself testified only that the physician who had entire charge of the case after her first day in the hospital and during her stay there stated "as his opinion" that the injuries were not serious. She complained at the trial that she was, in fact, suffering from internal injuries, but in at least two places in her brief it was said that the defendant's physicians failed to discover such injury. Clearly, then, they were not and could not be guilty of fraudulent misrepresentation as to that injury. If they failed to discover it, that might indicate negligence on their part, but that was no part of the issue made by the pleadings.

If the physicians were negligent or incompetent, the defendant would be liable for the results of such negligence or incompetence only in case it appeared that the defendant knew or should have known of the physicians' unfitness, and that, too, in a case where the pleadings presented that question. A physician's diagnosis is necessarily a matter of opinion, except where the ailment is external and visible. There was no evidence which even raised a suspicion that the statements made to the plaintiff as to her condition were not made in perfect good faith. Neither of the physicians who attended her for the defendant was present at the settlement, nor did they at any time take part in the negotiations for it. The attempt to invalidate the settlement was held to have wholly failed.—*Denver & R. G. R. Co. v. Ptolemy*, Colorado Supreme Court, 199 Pac. 541.

Care by Hospital of Delirious Patient.—In an action for damages for the negligence of a hospital in allowing a delirious patient to wander and hurt himself, it was held proper to allow practising physicians who qualified as experts to testify as to the character of attention a patient should receive at a hospital. As to whether such a patient, supposed to be dying, was delirious when he wandered and fell to the ground, or whether he did fall, and whether the hospital was negligent in not keeping closer watch over him, and whether such fall was the cause of his death, were held to be questions for the jury.—*Durfee v. Dorr*, Arkansas Supreme Court, 199 S.W. 376.

Unsuccessful Operation—Tort or Contract.—A complaint alleged that the defendant physician was employed by the plaintiff "to cure him of bladder trouble," that the defendant advised an operation, that the operation was performed, but left the plaintiff in a worse condition, that the plaintiff had suffered and still suffered great pain and had become weakened in body and his physical health and constitution had been greatly impaired, and that by reason thereof the plaintiff had suffered damages in the sum of \$10,000. It is held that the complaint did not state a cause of action for breach of contract to effect a cure, but an action sounding in tort for damages for the defendant's act or negligence, governed by the California statute requiring such actions to be brought within one year.—*Marty v. Somers (Cal.)*, 199 Pac. 411.

Military Medicine.

TREATMENT OF WOUNDS OF THE KNEE-JOINT IN WAR.

AFTER three years of warfare a large experience has been gained in the treatment of injuries to the bones and joints, and the knee, perhaps the most frequently involved of all, has come into its full share of study. The question of amputation in traumatism to the knee-joint may, after a careful survey of the practice of many experienced surgeons, be summed up as follows: Since any operation is usually performed on a subject in a very critical condition, the technique must be simple and carried out with celerity, but care must be taken to assure a thick flap. Such an amputation can be done by a good operator in about two minutes, more time than is required for the guillotine method, which is now looked upon with much less favor on account of the generally poor ultimate results obtained. The flap in case of knee joint amputation must be broad and circular, the bone being divided high up, in order to avoid an ulterior conical stump. No sutures should be used, and after hemostasis the wound is left completely open and dressings applied over all.

It is incumbent upon the surgeon to decide within the first few hours after seeing the case upon the treatment to be adopted. If there are extensive articular abrasions with a gaping joint, shattering of the epiphyses and diaphyses to a considerable extent, with vast laceration of ligaments, muscles, and skin, no hesitation should be permitted. The menace of infection rapidly increases after the lapse of the first ten hours, or even less, as the bacteriological researches of Lumière, Feisinger, Carrel, Policard, and Philip have amply demonstrated. The first three days following the receipt of the trauma are unquestionably the most critical and during which surgical activity should and must offer its greatest usefulness.

Some are of the opinion that arthrotomy, even for bone lesions, will result in recovery by first intention when resorted to within the first three days, if the joint wound is very carefully and exactly cleansed, and it is maintained that no matter how serious the infection, the process develops sufficiently slowly for the surgeon to be able to adopt conservative treatment if such seems feasible. Other equally competent surgeons believe that the synovial membrane is less resistant than the peritoneum and that after the lapse of twenty-four or thirty-six hours the results of arthrotomy are less favorable. At this phase the rapid progress of the infection may force the surgeon to discard arthrotomy and resort to the highest degree of joint drainage, namely, typical resection. But arthrotomy, when properly carried out, will expose the lesions perfectly, and not a few successful results may be obtained by this conservative procedure. As to amputation, it is indicated much more than during the first twenty-four hours following the injury. If the patient is not seen until after the lapse of three days a purulent arthritis will have developed, but even then a complete arthrotomy, with minute surgical cleansing of the joint, may still be essayed. All pus tracts must be followed up and freely ex-

posed and perfect drainage established. If the lesions to the bones composing the knee-joint are very extensive, if the attrition of the soft structures is considerable, and if the patient's general condition is precarious, typical or atypical resection must be done without delay. At a more advanced degree, and if smashing of the bones composing the joint is more extensive than the limits offered for resection, namely, from 5 to 8 centimeters for the femur and from 2 to 3 centimeters for the tibia, amputation must be done.

If now the case is not seen until after the lapse of a number of days, the infection has had free play so that one of three conditions will be offered to the surgeon. In the first, the infection, being of a mild type, has remained localized and the joint and muscular tissue will be seemingly in fair condition. Such cases should be examined by radiography, and pyoculture, cytodiagnosis, and all other means of clinical investigation will be of great help. If the bacteria are few and mild in virulence, if phagocytic action is good, if radiography and exploration of the joint do not reveal a foreign body or osteoarticular lesions of serious nature, immobilization of the joint may be sufficient, but more frequently the knee is swollen and painful on palpation, while the slightest movement causes suffering. One or several wounds from missiles will be seen or the joint may have been incised and drained, usually inadequately. If now an arthrotomy is done at once and freely enough to expose the joint cavity in its entire extent, the pathologically changed structures can be completely excised and all foreign material removed. But very often the pus will have burrowed between the muscles of the thigh and leg, the knee is distended, and radiography reveals great damage to the epiphyses.

In some cases the patient possesses sufficient physical resistance to withstand resection of the joint. Pyoculture and the clinical signs present indicate a mildly virulent infective process so that a conservative treatment can be essayed with the hope of saving the limb. But other subjects will be worn out physically, and the menace of septicemia is serious. The temperature chart of the "church spire" type tells the true situation, and amputation, as a life-saving measure, must then be done without delay.

Tropical Affections Observed in the Adriatic-Balkan War Zone.—Dr. Azzi, in *La Riforma Medica* for December 22, gives a synthetic review of this subject. The maladies in this zone pursue somewhat atypical courses. To possess value such observations should be made by men thoroughly conversant with tropical medicine, like Professor Castellani, who, as head of the Marine Hospital Service, has made numerous reports on the subject during the past two years. The first affection mentioned is a hemorrhagic type of malaria which simulates purpura and scorbutus. In 1915 a Servian regiment was attacked with what appeared to be scorbutus. The victims were pale and weak, covered with petechiæ and extravasations, presented epistaxis, hematemesis, melena, hemoptysis, and hematuria. Not a patient had

fever, but enlarged spleen in two patients promptly caused a blood examination to be made with the result that a quinine cure soon came to pass. Malaria has also simulated pernicious anemia, polyneuritis, and delirious and comatose states; not only did these types present no fever, but the spleen was often normal. Among other affections simulated were cerebral apoplexy and cerebrospinal meningitis, while among rare expressions were simulation of typhoid fever, Malta fever, tetanus, and sleeping sickness. The treatment-test is not infallible, for in certain of these expressions quinine failed to cure. Malaria can also simulate many local affections as indigestion, gastric ulcer, cancer of the stomach, cholecystitis, acute enteritis, dysentery, abscess and cirrhosis of the liver, acute hemorrhagic pancreatitis, appendicitis, etc. In cases in which quinine alone was inert it was given with benefit combined with methylene blue, arsenic, antimony, phosphorus, and picric acid. Nevertheless, quinine given by all of the routes and in high dosage was able to control the majority of cases, however severe.

Typhus and recurrent fevers occurred under numerous obscure expressions which are also described, but these affections cannot be termed tropical and we do not understand why Dr. Azzi includes them in his review unless it is because they cause much confusion in diagnosis. Pappataci fever is readily mistaken for typhus, but the latter is readily excluded by blood tests, since the leucopenia of Pappataci fever is replaced by a leucocytosis.

Among other tropical maladies encountered on this front are the following: febris columbensis (originally isolated by Castellani), Malta fever, kala-azar, quartan and intermittent fevers of non-malarial nature, spirochetic purpura, scorbutus, beriberi, splenomegalic icterus, filariasis, elephantiasis, endemic funiculitis, icterus as a clinical entity, when grave, is of spirochetous origin, and when mild appears to pass most frequently for paratyphoid. Among numerous diarrheas some are due to special parasites—flagellates like *Lamblia*, *Trichomonas*, and *Heteromita*. Notable in general is the pathogenic activity of the protozoa, whether flagellates, amebæ, or spirilla.

So-called tropical skin diseases are well represented, as numerous forms of tinea, tropical ulcer, Madura foot, saccharomycoses, aspergilloses, blastomycoses, sporotrichoses, and other dermatoses due to fungi. Some of the fungi give rise to chromatic lesions, red, black, etc.

Spirochetoses of the bronchial mucosa originally isolated by Castellani appear to have been well represented; these simulate the ordinary types of respiratory affection of the temperate zones more or less closely so that the sputum must always be closely studied for the presence or absence of the parasite. What is true of this protozoa also holds good for certain fungi, many of which attack the respiratory tract and simulate the familiar bronchopulmonary affections. Both types of parasite cause benign and malignant forms.

Prosthesis for Extensive Injuries Involving the Orbit.—While glass eyes answer for cosmetic eye

prosthesis when a stump can be fashioned, other resources are in demand for many war wounds in this region of the face. Cosmetic defects cause a profound psychic reaction when the subject feels himself repulsive to others. The familiar green patch or colored glasses of the unsightly blind man are examples of this character. The one-eyed man is the worse mental sufferer of the two, because for one reason the loss of one eye is a handicap in securing certain kinds of work. It must be remembered that wounded vanity is the least of the troubles of the blind, who may suffer from difficulties of facial mimesis and expression from the lack of both eyes and eyelids in addition to the consciousness of being repulsive. According to Angelucci in the *Giornale di medicina militare* for December 31, the lack of mimetic power must be keenly felt by the Italian who "suits the action to the word" with his ocular and palpebral movements in addition to the play of other facial muscles, hands, and shoulders. When a glass eye can be made to serve these troubles largely disappear. One outcome of the present war is a prosthesis much more extensive than a simple glass eye when fitted to a bulbar stump. When the orbit has been practically excavated an entire prosthesis is contrived to fill the orbit and this is enhanced by blepharoplasty. A further illusion is furnished by wearing a pair of ordinary spectacles. Comparative photographs show under the prosthesis great improvement in mimesis. The face shows natural repose instead of a set, strained expression. The subject once more is conscious of the presence of eyes even if he does not see. If one eye only is lost a monocle diverts attention from it and he will wear this only in company. The idea is by no means new, for according to the Talmud a gold eye was used—at least once—to mask the repulsiveness of an empty eye socket. The technique of blepharoplasty, as a result of the great demands upon it, should at least secure good cosmetic effects, even if functional restoration is necessarily in abeyance.

War Bacteriology in the Military Hospitals of Venice.—Bacteriological reports should give a fair idea of the morbidity of an army community from contagious and infectious diseases. A report published by Sangiorgio in the *Giornale di medicina militare* for December 31, shows that over 20,000 laboratory tests were made in the military hospitals of Venice during the year. Of this number two-thirds of the reports had to do with tests of the feces for the causes of choleric affections. The number of examinations made showed a great reduction in comparison with the previous year, which is well borne out by the fact that no case of cholera or of a cholera carrier came to light during the year. Whence it is evident that a great number of tests may or may not connote an absence of a given disease. In this connection may be enumerated 2,232 miscellaneous examinations of urine and 1,207 of sputum. Of serodiagnostics there were 135 Widal's for typhoid and 386 Wassermann's. Blood tests for bacteria were relatively few in number.

Next in frequency to stool tests for cholera and choleric affections come various tests for men-

ingitis. The actual number of cases of this disease seems to have been but 8, with 2 deaths; yet once again we see that a low morbidity can bring about an extraordinary amount of bacteriological activities. Of 2,487 tests for the presence of meningitis the vast majority must have consisted of examinations of the secretions of the nasopharynx for carriers. There is some doubt as to the efficacy of this form of prophylaxis, especially as the question of louse transmission has been raised. Such a theory would account in part for certain defects in our knowledge of this disease were it not for the fact that meningococcus disease is seldom a sepsis. The author, without giving figures, mentions bacteriological examinations for dysentery which may perhaps be included under "miscellaneous tests for bacteria" which number 267. Aside from 97 blood tests for malaria there is no specific mention of hemocultures. But four microscopical examinations were made in connection with skin lesions and but five for suspected food articles, in which the tests were evidently chemical.

The conclusion in regard to the great number of bacteriological tests with small number of positive results is entirely favorable and does not indicate a waste of effort. Eternal vigilance is the price of freedom from pestilence. We can conceive of an ideal community in which analysis might be overdone, but this could hardly be the case in a community engaged in active warfare and menaced constantly by epidemics which often have all the conditions which favor their development.

The Soldier's Heart.—Dr. I. Strickland Goodall in the Chadwick Lecture delivered for 1917 treated of the hygiene of the Soldier's Heart and formulated the following rules: (1) Insist on the more thorough and careful examination of recruits, not paying attention merely to valvular lesions, but to the history, form of heart, and especially its capacity for work. (2) Carry out the training of recruits more slowly, grading them according to their previous modes of life, physique, occupation, and age. (3) Insist on adequate rest during training, and periodic examination of the men. (4) The heart of a man of forty may be healthy but it will not stand the same strain as even a defective heart in a man of twenty. (5) Particularly examine and rest men after a febrile attack. (6) Treat all septic conditions of the mouth throat, etc.

Training Discharged Soldiers.—British Army Council Instructions have been issued relating to the continued treatment and training of discharged soldiers. The Ministry of Pensions and War Pensions Committees in the boroughs and county boroughs and in other large towns are charged with the duty of securing any medical treatment on training for industrial life that a discharged soldier may need. The instructions suggest that officers in charge of hospitals should be placed in touch with such committees. So long as in-patient treatment is required and accommodation is available, soldiers will be retained in appropriate hospitals, and, if considered unfit for further service, will be brought before the invaliding board. In addition to hospital treat-

ment, an appropriate course of technical training may for many cases be desirable. The provision of such means of training rests with the Ministry of Pensions and officials of hospitals are advised to assist such cases with advice.

Hospital Ship Torpedoed.—The British hospital ship, *Glenart Castle*, was torpedoed in the Bristol Channel and sunk within seven minutes. She was outward bound and had no patients on board. None of the seven nurses that were on board are reported saved. Of the 182 persons on board only 38 have been reported as saved thus far.

Glasses for the United States Navy May Be Sent to New York.—Owners of sea glasses and binoculars who may wish to respond to the appeals that they be loaned for use in the navy may send or leave them at the naval recruiting station at 34 East Twenty-third Street, New York City. The need for these glasses is still very urgent.

Gift for Relief Work in Palestine.—A gift of \$100,000 for the medical unit of Hadassah has been appropriated by the Joint Distribution Committee of the American Jewish Relief Committee. The medical unit expects to leave for Palestine in a few weeks. The British Government has given assurance that it will cooperate in every way to secure a safe and speedy transportation of the medical unit.

In Favor of the Owen and Dyer Bills.—The New York State Committee of the medical section of the Council of National Defense, of which Dr. George D. Stewart is the chairman, is sending a letter to all medical organizations in the State urging them to send to the New York Senators and Representatives in Congress resolutions endorsing the Owen and the Dyer bills recently introduced into the Senate and House respectively providing that officers of the Medical Reserve Corps be given equal rank with those of the Regular Army and that they have the same eligibility to advanced rank as is now provided for the line officers. It is pointed out that the passage of these bills is of the highest importance to the medical profession as an evidence of the recognition of the patriotic services of that profession which has furnished to the Federal Service a greater proportion of its members than any other.

Federal Board for Vocational Education.—This body has made public its plans for the re-education and rehabilitation of disabled soldiers and sailors. It estimates that 100,000 out of every 1,000,000 soldiers sent overseas will return to the United States during the first year of fighting, and that 20,000 of these will need some kind of vocational reeducation. The first of these men will come back during the summer of 1918, and adequate provision must be made for them before they are actually in hand for training. A comprehensive Federal system for the reeducation and placement in wage-earning occupations is presented which involves a central administrative agency in Washington, the coordination of that agency with similar public, semi-public, and private agencies, the establishment of "curative workshops for the treatment of war cripples, to-

gether with a complete system providing for subsistence and pay during the period of reeducation." Emphasis is placed on the immediate and pressing demand for the training of teachers of occupational therapy to take care of the handicapped men on their return. It is estimated that for every 1,000,000 men overseas 1,200 teachers will be needed. The Federal Board presents in this bulletin an outline of an emergency course covering eight weeks for the training of teachers. The bulletin discusses therapy and the equipment needed for the various groups of disabled men.

Medical Officers Discharged Since War Began.

—A statement issued by the Committee on Public Information shows that from the declaration of war to February 23 the Surgeon General of the Army has discharged 1,050 officers of the Medical Reserve Corps other than 31 removed by death. Of these discharges, 411 were for physical disability, 154 for inaptitude for the service, 306 to join other branches of service, 59 because of domestic difficulties, 32 because they were needed by committees, hospitals, schools, etc., and 88 resigned. All of those whose dismissal was in considerable degree due to inefficiency or incompetency are not isolated under "inaptitude for service," since the latter reason had weight in many cases otherwise classified. During the same period there have been 2,265 promotions of Medical Reserve Officers. The total strength of the Medical Corps on February 23 was 15,694. At the outbreak of the war there were 877 medical officers, including Regulars and Medical Reserve Officers on active duty.

Rockefeller Gifts to War Work.—At the annual meeting of the Rockefeller Foundation, on March 1, additional gifts to war work to the amount of \$187,281 were announced. Of this sum, \$125,000 is to continue the war demonstration hospital of the Rockefeller Institute, \$50,000 for the medical division of the National Research Council of the Council of National Defense, and \$12,281 for other medical war research and relief work. Dr. Hermann M. Biggs was elected a member of the International Health Board of the Foundation. The Executive Committee of the Foundation for the year 1918 has among its members Dr. George E. Vincent and Dr. Simon Flexner.

New Naval Hospital.—A number of frame buildings have been acquired by the Government on a site adjoining the naval cantonment at Pelham Bay Park, which are to be used as a general hospital for the United States Navy. The hospital is to be similar to Base Hospital No. 1, better known as the Columbia University Base Hospital. The proposed naval hospital will accommodate 2,000 patients.

Deaths in the Service.—Captain Frank S. Pratt of North Bend, Ore., died of pneumonia, at Fort Russell, Wyo., on February 11, aged 54 years. He was a graduate of the University of Oregon Medical Department in 1908. He enlisted in the service last fall and was recently advanced to the rank of Captain.

Physical Examination for Red Cross Aids.—Arrangements have been made by the American Red Cross whereby the Life Extension Institute

of New York will make a physical examination of applicants for service in relief work overseas. The examinations will be made not only at the head office of the Institute in New York, but in the home towns of the applicants when this is necessary. All such examinations will be arranged by the Bureau of Personnel of the Red Cross. The Life Extension Institute will make arrangements with physicians examining applicants for their immunization against typhoid and paratyphoid fever and smallpox. The workers who pass the physical examination will be given such instruction and suggestions in hygiene as will tend to make them better able to bear the strain of war work.

Public Health Service Plans to Combat Meningitis.—The United States Public Health Service has issued a statement which gives the assurance that it has a definite plan for dealing with epidemics of cerebrospinal meningitis. When an epidemic threatens to exceed ordinary proportions the service will detail an epidemiologist, with the necessary laboratory equipment, to investigate and cooperate with local authorities in the control of the disease.

McGill University, Montreal, has been presented by the Carnegie Corporation with a gift of \$1,000,000 in recognition of its devoted services toward Canada's part in the war. In addition to its active part in military affairs, McGill University has maintained a general hospital in France with more than 2,000 beds.

A Study of Trench Fever has been undertaken by American surgeons in France. Sixty enlisted men of the Sanitary Corps, U. S. A., have volunteered for the experiments; some have received injections of blood taken from men suffering from trench fever, and others are serving as hosts to body lice taken from men with the disease. With the approval of General Pershing a call for volunteers was made and virtually every member of the 101st, 102d, and 104th Field Hospitals and the 101st, 103d, and 104th Ambulance companies offered to submit to the experiment.

Coast Hotels for War Hospitals.—A preliminary survey of the New Jersey Coast resorts has resulted in four well-known hotels being designated by Surgeon General Gorgas as peculiarly adapted for use as army hospitals. These hotels include the Lakewood Hotel, at Lakewood; the New Monmouth and the Essex and Sussex, at Spring Lake; and the New Monterey, at Asbury Park. General Gorgas has also asked authorization to establish hospitals at Cape May and Colonia. These hotels will afford accommodation for more than 5,000 men and can easily be arranged to provide for 7,500. It is probable that Surgeon General Gorgas's recommendation will be approved by the Government within two weeks.

Gift to Hospital Ships.—The National Society of the Colonial Dames of America has raised \$50,000 for the purpose of equipping the operating rooms of the two hospital ships, *Comfort* and *Mercy*, now being fitted out for the use of the Navy. The gift not only provides the ordinary equipment, but is supplying moving picture reels, phonograph records, and other articles for the entertainment of the men.

ENCOURAGING THE PARALYTIC TO RECOVER.

WE are all aware by now of the possibilities of re-education in compensating for loss of tissue. Such surprising results have been obtained both experimentally, where first one motor area and then both were excised in monkey's brains, and practically, where paralytics of the sort usually termed chronic and hopeless have been restored to comparative health, that we look upon even the least promising case with a fair degree of optimism. The secret of the method lies in keeping everlastingly at it, working with the patient every day, and setting the mark of progress a little farther ahead all the time. One point, however, is entitled to special comment, and that is the matter of enlisting to the utmost the patient's aid.

So often in these cases we have to do with a temperamental laziness or indifference or pessimism, or else an apathy closely associated with and perhaps caused by the actual damage done to psychic centers by the cerebral lesion responsible for the paralysis, that we are apt to be discouraged at finding our efforts nullified to some extent by the *vis inertiae* of the patient. In such cases there are three ways of getting cooperation: holding out the prospect of recovery, making the exercises interesting, and representing progress graphically.

The first method it is probably unnecessary to emphasize, as it is such an integral part of the practitioner's armamentarium. The second method is one whose importance should never be underestimated. All of us who have at various times in the past decided that our biceps needed hardening, or our chest expanding, and to that end have purchased wall exercisers or dumbbells, with the praiseworthy intention of devoting 15 minutes a day to them, know how difficult it is to keep such a resolution. Likewise, the patient, if put at doing exercises over and over of whose rationale he is unaware and the effects of which he cannot see, is apt to grow extremely bored with them, and either neglect them altogether or slight them fearfully. On the other hand, by utilizing the "play spirit" we can be assured of his unflagging devotion to the business in hand. Even so simple a game as trying to pitch

a tennis ball into a basket several yards off, and registering the number of successes, will rouse interest; or casting a dart at a target; anything, in short, which permits of a score being kept will rouse the patient to efforts to "beat his own record."

Finally, the recording of the patient's progress by means of charts is helpful. The larger and more striking these are the better. Big black and red lines, showing decided upward sweeps, are good. If the patient is able to pick up a tennis ball with the paralyzed hand in 40 seconds the first day, for example, and 38 the second, and 30 the third, this progress should be represented by a curve going upward, and the patient will soon feel eager interest in it, and try each day to force it higher.

The ingenious physician will thus find many ways of stimulating the patient's interest, and be rewarded by finding that his paralytic patients make remarkable progress on the road to recovery, and that he does not have to be constantly urging them to persist in their exercises.

THE MANAGEMENT OF ABNORMAL BLOOD PRESSURE

IN the discussion of high blood pressure and its significance it is sometimes forgotten that hypertension is an effort to establish circulatory compensation and therefore is in itself physiological. According to Thomas E. Satterthwaite, in an article published in *International Clinics*, Vol. III, Series 27, this point should be always remembered in the management of hypertension. The diet should be regulated so as to limit the amount of protein and in general to prevent the formation of acids in the system resulting from the development of putrefactive processes. Bulgarian sour milk or ordinary buttermilk is sometimes useful in combating intestinal toxemia, and it is best combined with vichy in the proportion of from one-eighth to one-half. Fresh vegetables and milk should be taken freely. No pastry, coffee, tea, alcohol, or tobacco should be permitted, or very sparingly taken. The Karell treatment of a glass of milk at 8, 10, 4, and 8 for two consecutive days may be helpful in acute cases, the patient resting in bed. Rest is also important, but properly controlled exercise, active or passive, according to the severity of the symptoms, may be of service. No excitement of any kind should be permitted. Constipation should be avoided and care should also be taken to see that there is no excessive functioning of the adrenals and the other ductless glands, the secretions of which, if in excess, produce hypertension.

Satterthwaite is greatly in favor of the use of the high frequency current, given two or three times a week in seances of eight to ten minutes. As for drugs, iodine should be administered in moderate doses, and iron if a tonic is required. Nitroglycerin, alone or with other drugs, may be given in sufficient doses to reduce the pressure, if that is desirable,

but it should not be administered in doses sufficient to produce a prolonged headache. On the other hand, the use of digitalis need not be feared in cases of high blood pressure. According to Burnet, writing in the *Medical Press* of August 21, 1912, the tincture of digitalis does not raise the pressure—a fact, if it be a fact, which is not generally known. The use of chloral hydrate is not recommended, but sometimes the bromides give satisfactory results. Satterthwaite uses aconite in one-minim doses more than any other drug.

Of course, in the treatment of hypotension, rest, mental and physical, is very important, and digitalis, strychnine, and preparations of iron or manganese are helpful. If the hypotension is due to adrenal insufficiency, Satterthwaite has found two-grain doses of the dried gland three times a day useful, or $1\frac{1}{2}$ grains of the dried adrenal with $\frac{1}{10}$ grain pituitary gland about three times a day. Such patients should have plenty of outdoor air and mild passive exercises and massage.

It should be borne in mind that in all cases of abnormal blood-pressure hypertension has, on the whole, a far more unfavorable prognosis than hypotension, which, except after loss of blood in shock, in acute cardiac dilatation in the course of infective diseases, is not a cause of immediate alarm. For the most part, hypotension indicates mathematically the degree of exhaustion in wasting diseases, such as tuberculosis. On the other hand, hypertension is usually associated with arteriosclerosis, when the degree of it measures approximately the danger from nephritis or cerebral hemorrhage.

TUBERCULOSIS AND MILITARY ORGANIZATION.

PULMONARY tuberculosis is still the most prevalent, and, on the whole, the disease which is most destructive to human health and life in civilized countries. So far as the spread of tuberculosis is related to war, the situation is somewhat confused. It has been widely advertised that the influence of war on tuberculosis has been powerful, and evidence in support of this assertion has been adduced from France. The statement has been frequently made that since the war tuberculosis has increased enormously there, and that this increase is due entirely to the non-enforcement of well-timed measures by the responsible authorities. On the other hand, Dr. Arnold C. Klebs (*Naval Medical Bulletin*, Vol. II, No. 4) agrees with many of those who have the best means of knowing, in the opinion that this view is not correct, or, at any rate, is greatly exaggerated, and he thinks that the "war tuberculosis program" formulated by the Army and Navy authorities in this country is not altogether wise, and he lays emphasis on the fact that an attempt to base the prevention of tuberculosis on methods of prophylaxis against acute diseases would be a short-sighted blunder.

Klebs points out that the assumption that the

healthy life led by the enlisted men of the army and navy tends to good health, while it contains the elements of truth is somewhat exaggerated. When, however the service is prolonged, and especially in actual warfare, the strain becomes great, sanitation and hygiene are neglected, particularly in trench warfare and when billeting in private houses has to be resorted to.

Training at home should anticipate these conditions, and therefore, in Klebs' opinion, "health-resort standards," or the elaborate hygienic and sanitary arrangements of many of our public institutions, ought to be barred from military establishments. To teach men to harden themselves, to avail themselves almost instinctively of healthful opportunities wherever they are present—washing, bathing, etc.—is essential. In our aim at simplification it ought to help when we realize that practically all our prophylactic measures come under the heading "cleanliness." Thus cleanly habits and clean open air are now our mainstays against tuberculosis. The relative importance which the specific and non-specific factors have in the production of tuberculosis must determine our preventive measures, as it should guide also our therapeutic methods.

The writer thinks that a new profession, that of the medically trained educator, the "social physician," will have to cope with the problem of the general management of the tuberculous, for which the general physician, with his specialistic preoccupations, is little fitted. The new army and navy might well offer an immense and most fertile field for the raising of such a profession, which, at present, is recruited almost entirely from amateurs—well-to-do, philanthropically-inclined physicians, who will give some of their precious time to committee meetings, but to very little independent thought or work. The tuberculosis problem is an important phase of military organization, and the suggestions made by Klebs are valuable.

REPORT OF THE SURGEON GENERAL OF THE NAVY.

THE report of the Surgeon General of the Navy for the fiscal year 1917, which has been published recently, gives interesting information regarding the increase of the activities of the bureau owing to the conditions of war. The personnel of the Medical Corps of the Navy had long been insufficient for its requirements, and the material increase in total personnel and the reapportionment of grades and ranks in line and in staff corps, established by the act of August 29, 1916, relieved an embarrassing situation. Prior to the passage of this act the authorized strength of the Medical Corps was 345. The increase provided for an immediate allowance of over 600, with a permanent increase, at the discretion of the President, to over 800. This latter figure, by executive order, has been made permanent, and by the act of May 22, 1917, a considerably further temporary increase has been authorized. An

energetic campaign was inaugurated to secure desirable candidates but up to early in 1917 it seemed that there would be a good deal of difficulty in obtaining the necessary quota. However, at that time the Secretary of the Navy requested all the State boards of licensure to approve the advance graduation of selected medical students who would be recommended for enrollment in the Naval Reserve Force with a view to subsequent examinations for appointment. The State boards immediately fell in with this plan, as did the deans and faculties of all the class A medical colleges and special examinations were arranged for the selected students. In this way three hundred and twenty-nine officers were obtained for the Naval Reserve Force, all of whom have been reexamined recently for commissions in the Medical Corps of the Navy, and 70 per cent have been passed as assistant surgeons in the Navy.

It would be impossible here to do more than touch upon some of the activities of the Medical Corps of the Navy connected with war service, and it will suffice to refer to a few of these. Great care has been taken to protect recruits from contracting contagious diseases, but in view of the fact that such diseases have been very prevalent throughout the United States during the past winter, and that a large number of enlisted men in the incubation stage were massed together in training camps, it was impossible to prevent epidemics. Consequently, the exercise of great sanitary skill was required to stamp them out and at the same time to permit the training to proceed without serious interruption. At the present time it is stated in the report that health conditions in the service are excellent, and the sick rate compares favorably with that under peace conditions.

The Hospital Corps has been enlarged to adequate dimensions, so far as personnel is concerned, but a system of training had to be initiated. Now the Hospital Corps of the Navy has a proper number of men and a fairly effective system of training. Finally, it may be said that the situation as regards venereal diseases has considerably improved.

THE FRANCE OF TOMORROW AND THE DOCTORS.

A WRITER in the *Journal de médecine de Bordeaux* for January, 1918, states that he has rarely seen the members of any profession more discontented with the outlook than are the medical men of France. This feeling is expressed by a caustic railery, which is heard especially in the fighting zone; but the discontent finds no expression in insubordination. The motivation of this feeling is due to several factors. After the tremendous exertions of the war, the return of peace will bring a reaction in which the medical man will find himself in a peculiar position. The artisan will be confronted with no problem, nor will the bureaucrat, for they will step naturally into their former spheres. Intellectuals will resume their writing and teaching. But for the physician the struggle for existence will be intense, and neither the extent nor complexity of

the problem can now be foreseen. Many medical men have devoted the years of war to a narrow routine of work, such as applying first dressings. They have, of course, become experts along certain lines. But the physicians who were sent home as unfit, or who were too old for service have had special opportunities to build up followings, and there is not much likelihood that they will lose by the return of the military men. These, who have been shoulder to shoulder with the actual fighting men, must, like the latter, be favored in some way. The State can aid them, as can also corporations, and they should be given preference as city physicians, railway surgeons, etc. A point scale should be created, so that the longer the service at the front the better the claim to some salaried position, as an employee of the State, department, or municipality. Such an arrangement would, of course, bear hard on those who from shortness of term would be ineligible, but no scheme can be devised that will work for the good of all.

News of the Week.

Funds Needed to Fight Tuberculosis.—The Society for the Study and Prevention of Tuberculosis is making an appeal for funds to increase the facilities for care of tuberculous patients. A statement issued by the association claims that recent medical examinations in the new army and navy bring out the fact that there are about ten active cases of tuberculosis for every death from it. According to estimates by the association, there are in the United States at the present time between two and three million tuberculous individuals. An average of about 2 per cent. of the men of draft age are found to be tuberculous.

Deaths from Illuminating Gas.—During the eight weeks ending February 26 the number of deaths due to illuminating gas in New York City has been 232, according to the records of the Health Department. This is 87 more than during the corresponding period of last year, when there were 145 fatalities from this cause. An investigation of these deaths by the Health Department shows that practically all of them could have been avoided had the danger been understood and simple precautions taken. Health Commissioner Amster has asked the acting school superintendent to aid in instructing the public regarding the danger of illuminating gas poisoning and how the peril may be avoided.

"Adequate Ventilation" Defined.—A resolution adopted by the Health Department of New York City on December 11 states that in the interpretation of the Sanitary Code the term "Adequate Ventilation" will be as follows: (1) The temperature of rooms during periods of occupancy should register preferably from 60° to 70° Fahrenheit at all times, except when the outside temperature exceeds 60 degrees. This does not apply to rooms used for special purposes, such as industrial places where high or low temperature are essential and unavoidable. (2) The relative humidity in occupied rooms should not exceed 70 per cent., except when the outside bulb temperature exceeds 59°. (3) The carbon dioxide in occupied rooms of all classes should not at any time exceed 10 parts in 10,000 volumes of air in any part of the occupied spaces

of the rooms. (4) The dust particles in the air of occupied rooms in all classes of buildings should not exceed 1,000,000 per cubic foot. (5) The bacterial content should not exceed 100 per cubic foot. (6) The air of occupied rooms should be free from objectionable odors.

Plans for Drug Control.—The Whitney Committee has presented its report to the Legislature, together with a plan for the control of the drug evil. According to the proposed plan, a board is to be appointed within the State Department of Health. There is to be a commissioner of drug control, with a sufficient administrative force to provide for co-operation with the Federal Internal Revenue Bureau to use as far as possible the information obtained by Federal agents and inspectors. The drug commissioner is to have power to make rules and regulations for the control of the drug traffic. According to estimates furnished by the committee, about 2 per cent. of the population of New York City are drug habitués, and a larger percentage of the population of smaller communities and rural districts. The committee finds that the use of narcotic drugs is greatly on the increase, and ascribes this to the war and the lack of proper regulation of the traffic.

New York Health Records for 1918.—In response to a request from the Mayor that the heads of all city departments give an accounting, Health Commissioner Amster reported that for January and February, 1918, the death rate of the city was 15.51, as against 16.97 for the first two months of 1917. This represents an actual saving of over 2,600 lives for the first two months of the present year. The report states that the number of deaths from lobar pneumonia for these two months is 450 less than for January and February of 1917, when the rate was unusually high. The death rate from tuberculosis for these two months gives promise of an improvement over 1917, when it was a little in excess of the rate for 1916. There were 22,021 births reported for January and February, 1918, as against 24,227 for the corresponding months of 1917. The marriages for these two months, in 1918, numbered 8,389, as against 11,187 for the same period of 1917. The cause of this falling off is being studied by the Health Department.

Courses of Instruction in Contagious Diseases.—The courses of instruction in contagious diseases given at the Willard Parker Hospital for the past three years are to be repeated this spring. The courses are designed to meet the demands of physicians for opportunities to perfect themselves in their knowledge of contagious diseases. Each course will consist of eight lessons, six of which will be devoted to clinical and bedside instruction. The first course will begin on March 5, at 2 P. M., at the Willard Parker Hospital. Similar courses will be conducted in April and May, if there are a sufficient number of applicants. Those wishing to participate may do so by registering with the Bureau of Public Health Education, Department of Health, 139 Centre Street, New York City.

A Cure for Malta Fever.—Prof. M. A. Vincent of the Paris Academy of Medicine is reported to have found a curative and preventive vaccine for Malta fever.

Dr. Leo Buerger of New York has been ap-

pointed professor of genitourinary diseases in the New York Polyclinic Medical School and Hospital.

Dr. A. I. Ringer, formerly Assistant Professor in Physiological Chemistry at the University of Pennsylvania, has been appointed special consultant in Diseases of Metabolism at the German Hospital, New York City.

Dr. Seth M. Milliken has been appointed assistant attending surgeon of the First Surgical Division of the Roosevelt Hospital, New York.

Dr. William J. Robinson of this city, editor of the *Critic and Guide*, is reported in the *New York Times* to have been arrested for sedition, and released under 5,000 bail.

Charitable Bequests.—The will of Mrs. Mary Elizabeth Turnure bequeaths \$10,000 to the New York Association for the Blind, a like sum to the Home of Rest for Consumptives, and to a hospital in Syracuse, to be designated by Grace Church of Baldwinsville, N. Y., \$5,000.

The Stamford, Conn., Hospital is the recipient of a bequest of \$5,000 by the will of Mrs. Enos B. Lockwood.

Opportunity to Study Pediatrics.—The Home of Hebrew Infants, with an average census of 400 children under five years of age, seeks a resident physician, man or woman. The service offers an exceptional opportunity to study pediatrics and to participate in research work. The position carries a salary of \$75 to \$100 a month, with maintenance, depending upon the applicant's ability and previous experience. Applications may be made to Alfred Hess, 16 West Eighty-sixth Street, New York City.

Civil Service Examinations.—Examinations for superintendent of County Tuberculosis Hospitals of Niagara and Steuben Counties, at salaries of \$1,500 to \$3,000, and maintenance, have been announced by the Civil Service Commission. An examination will also be held to provide eligibles for the position of assistant physician in the State hospitals and similar positions in various State and county institutions. The salary in the State hospitals is \$1,200, with a yearly increase to \$1,600. These examinations are open to men and women. Application should be made to the Civil Service Commission, Albany, N. Y., before March 18, 1918.

The Tri-State Medical Association, which met in Charleston, S. C., on February 21, elected the following officers: *President*, Dr. Robert S. Cathcart of Charleston; *Vice-Presidents*, Dr. F. A. Coward of Columbia, S. C., Dr. L. A. Crowell of Lincolnton, N. C., and Dr. Douglas Vonderhoof of Richmond, Va.; *Secretary-Treasurer*, Dr. Robert E. Hughes of Laurens, S. C. The new members of the *Executive Council* are: Dr. R. C. Bryan of Richmond, Va., Dr. E. C. Register of Charlotte, N. C., and Dr. F. H. McLeod of Florence, S. C.

Obituary Notes.—Dr. JAMES G. RIDDICK of Norfolk, Va., died at his home, after a lingering illness, on February 15, aged 56 years. He was a graduate of the College of Physicians and Surgeons, Baltimore, in 1883. He served as Mayor of Norfolk for ten years and as health officer for twelve years.

Dr. THOMAS C. BIDDLE died of pneumonia at his home in the Topeka, Kan., State Hospital, of which he was superintendent for nineteen years, on February 16, aged 60 years. He was a graduate of Rush Medical College, Chicago, in 1881, and for-

merly superintendent of the Osawatomie Hospital. He served for some years as physician and surgeon with the Twenty-first Kansas Volunteers. Several weeks ago he was appointed chairman of the Kansas State Medical Advisory Board.

Dr. ARTHUR J. HOLMQUIST died suddenly at his home in Denver, Col., on February 13. He was a graduate of the Denver College of Medicine in 1897.

Dr. AMBROSE J. GALLISON, a graduate of the Dartmouth Medical School, in 1887, and for fifteen years secretary of the Thurber Medical Association of Milford, died of angina pectoris, at his home in Franklin, Mass., on February 15, aged 62 years.

Dr. CHARLES GUSTAVUS McMANAWAY of Charlotte, N. C., a graduate of the Medical College of Louisville, Ky., in 1883, died of cancer of the liver, on February 15, aged 60 years.

Dr. WILLIAM J. CRONYN, a graduate of the University of Buffalo Medical Department, in 1870, and a Civil War Veteran, died at his home in Milwaukee, on February 20, aged 69 years.

Dr. ELBRIDGE H. KING, a graduate of the Detroit College of Medicine in 1870, and for some years coroner of Muscatine County, died at his home in Muscatine, Wis., on February 13, aged 73 years.

Dr. WILLIAM BUTLER PRATHER, a graduate of the Atlanta Medical College, Georgia, in 1874, died, following a stroke of paralysis, at his home in Seale, Ala., on February 19, aged 71 years.

Dr. AUGUSTUS STEELE ROSE of Fayetteville, N. C., a graduate of the University College of Medicine, Richmond, Va., in 1901, died following an operation for appendicitis, at the Highsmith Hospital in that city, on February 15, aged 45 years.

Dr. HENRY B. STEHMAN, a graduate of Jefferson Medical College, in 1877, died at his home in Pasadena, Cal., on February 16, aged 66 years.

Dr. ELLA ELIZA SEVERANCE, graduate of the Boston University School of Medicine, in 1901, died at her home in Lynn, Mass., on February 18, aged 61 years. Dr. Severance practised medicine for some years in Camden, N. J.

Dr. JOHN H. McMULLEN, a graduate of Harvard Medical School, in 1900, died suddenly at his home in Lynn, Mass., on February 21, aged 41 years.

Dr. GEORGE ROEHRIG, a graduate of Jefferson Medical College, Philadelphia, in 1890, died, after a long illness, at his home in Denver, Col., aged 56 years. He was for many years a member of the St. Luke's Hospital staff and surgeon for the Burlington Railroad.

Dr. AUGUSTUS P. TAYLOR died at his home in Thomasville, Ga., after a lingering illness, at the age of 71 years. He was a graduate of New York University Medical College, in 1870, and for a number of years a member of the State Board of Health.

Dr. JOHN A. STEVENS, a graduate of Jefferson Medical College, in 1883, died at his home in Clinton, N. C., on February 13, aged 58 years.

Dr. EDWIN I. HARRINGTON died at his home in Yonkers, N. Y., after a prolonged illness, on February 24, aged 62 years. He was a graduate of Jefferson Medical College in 1881, former health commissioner of Yonkers, and ex-president of the Jenkins Medical Society of Westchester County. Dr. Harrington was consulting surgeon to St. Joseph's Hospital, and consulting physician to the Home for the Aged at Yonkers.

Dr. HARRY VARLEY BINGHAM, a graduate of the New York Homeopathic College, in 1905, died suddenly at his home in Madison, N. J., on February 24, aged 41 years.

Dr. GEORGE FRANCIS MORRIS of New York City died suddenly on February 25, at the age of 65 years. He was a graduate of the Albany Medical College in 1878, and for many years connected with the Department of Health of New York City.

Dr. RACHEL B. LAIN, a graduate of the Hahnemann Medical College, Chicago, in 1890, died following a stroke of paralysis, at her home in Vallejo, Cal.

Dr. GRANT T. JOHNSON, a graduate of the Kansas City Medical College, in 1893, died of pneumonia at his home in Wamego, Kan., on February 14, aged 55 years.

Dr. JOHN C. MCGILLIVRAY, a graduate of Trinity College, Toronto, in 1889, and for many years police surgeon of Denver, Col., died of erysipelas, at his home in that city, on February 11, aged 54 years.

Dr. WILLIAM SEIDLER, a practising physician of Minburn, Iowa, died at his home in that town on February 13, aged 91 years.

Dr. EDWARD MILTON RICHMAN, a graduate of the University of Pennsylvania Medical Department, in 1898, and one of the founders of the Newark, N. J., Private Hospital, died in that institution on March 2, aged 45 years.

Obituary.

SAMUEL GIBSON DIXON, M.D., LL.D.

BRYN MAWR, PA.

DR. SAMUEL GIBSON DIXON, Commissioner of Health of the State of Pennsylvania, died in Philadelphia on February 26, at the Hospital of the University of Pennsylvania, at the age of 66 years. He was graduated from the law department of the University of Pennsylvania, in the class of 1877, and from the medical department in 1886. In 1888 he was elected professor of hygiene and dean of the auxiliary department of medicine in the University, but he soon took up independent laboratory investigation at the Academy of Natural Sciences, where he made intensive and productive studies of the tubercle bacillus and the experimental production of immunity to tuberculosis. In the course of this work he devised a lymph from the bodies of dead tubercle bacilli that has been used successfully in the treatment of tuberculosis. He had been Pennsylvania State Commissioner of Health since the creation of this office in 1905. He was president of the Academy of Natural Sciences in 1896. He was a councillor of the American Philosophical Society, one of the founders of the Pennsylvania Society for the Prevention of Tuberculosis, a director of the Philadelphia Zoological Society, a trustee of the Wistar Institute of Anatomy, a Fellow of the College of Physicians of Philadelphia, a member of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association. The degree of Doctor of Laws was conferred on him by the University of Pennsylvania in 1909. He was the author of "Physiological Notes," 1886, and of many articles on bacteriology, hygiene, and other subjects in medical journals and in the volumes of the Proceedings of the Academy of Natural Sciences.

Correspondence.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

MAKING SURGICAL DRESSINGS—PHYSICAL TRAINING OF THE MEN.

PARIS, Jan. 8, 1918.

UNDER direction of the Red Cross the women of the American Colony have organized to make surgical dressings for the army hospitals. The American Ouvroir, organized by Mrs. E. W. Wilson, has been doing more than its bit recently to meet the demand for surgical dressings for the American troops. The appeals from women who are doing their bit, as well as Mrs. Austin's personal calls for dressings, have spurred American women on so as to have the number of dressings ready for American hospitals by the time our soldiers require them. The French members of the ouvroir as well as the Americans have worked with the utmost energy for the first gift to the United States fighters.

In acknowledging this gift the Red Cross wrote that it was a joy to handle such beautifully made things and at the same time urged upon the workers the urgent necessity for more dressings. The first American troops had fallen and at any moment they might be called upon to supply dressings in large quantities.

Mrs. Wilson's ouvroir was one of the first to open under Miss Thackara at the outbreak of war, and has been doing a good share of the surgical dressings work ever since. A group of about twenty women meet on Mondays, Wednesdays, and Fridays to carry on the work.

It is a good augury for the morale of our troops that everyone seems particularly interested in their welfare, and recently quite a discussion has sprung up as to the best form of physical training to employ to make them fit and equal to the unusual strain they are to be put to. Quite an effort has developed to introduce the employment of jiu-jitsu, not only as an exercise but as a useful means of self defense in personal encounter of which there is a great deal in the present form of warfare.

Dr. James H. McCurdy, director of physical exercise in connection with the American army in France, said upon this subject that the first thing was to obtain military efficiency. That is what all looked for and the best step in individual efficiency had been bayonet exercise. Nothing would give the American soldier so much confidence as this. The pushing of mass athletics would be also a great help.

This mass athletics is athletics carried out for the majority and not for the minority of the men; for the mediums and not for the pick of the lot. In mass athletics every man in the company gets into the game. The kinds of sport adopted are running in the different classes for speed and for endurance; jumping in various classes, wall-scaling, trench jumping, climbing out of the trenches and so on. Men can learn to do these things. We must build up the men who are inferior in sports and exercise, and it is remarkable how much can be done to build up the physique of ordinary men by keeping them massed together. A big improvement is always possible. And this class of men will do

as much good as the best athletes, if not more. The men are being made efficient in that they are able to do what they are expected to do in the army and to do it well and quickly. The Y. M. C. A. has a regular schedule of games in the rest camp for men who have returned from the fighting line. This type of work is being pushed by Major G. Goulin, of the Third British Army, and by Captain E. N. Smith, athletic director for the Y. M. C. A. in the Canadian army. The best company should represent the regiment rather than the best men from all company teams. This makes training and discipline easier. Wherever possible the cooperation of the Y. M. C. A. is recommended in the organization of the mass games as a part of the physical drill periods for all men, involving activity which will increase alertness and physical efficiency. This has been done in some of the camps in the United States. The British army has also added to the ordinary drill games which increase agility and endurance. The mass regimental games recently organized at one of the ports of entry in France consisted of trench jumping, running, and company soccer.

In a recent trial of mass athletics in a port in France 28 per cent. did not qualify in a jump 6 ft. wide; out of 1,400 men competing in the 220 yards dash 17 per cent. did not qualify in 30 sec. In an attack, Dr. McCurdy says, it will save lives if we can improve the poorer athlete serving as a soldier. The lower-grade athlete in the army, say 40 per cent. in physical efficiency, is the element that often holds it back from aggressive work where high physical efficiency is required. Bayonet exercise gives the soldier confidence in his ability to look after himself. On the other hand, mass athletics has a counteracting effect to the softening tendency, physically speaking, of trench life. In the recent test referred to 1,400 men jumped over a trench 6 ft. wide in less than ten minutes. That gives an idea of what not only the best man can do, but all the men can do. Then the same 1,400 men ran 220 yards, and then they played soccer. I devised an arrangement for keeping up interest in company soccer, where one company plays against another company. It has had fair trials and the results are very satisfactory.

Progress of Medical Science.

The Boston Medical and Surgical Journal.

1. Acute Lobar Pneumonia. F. C. Shattuck and C. H. Lawrence.
2. Recent Treatment of Lobar Pneumonia. Thomas F. Leen.
3. Recruiting Notes. Harold W. Dana.
4. The Army Surgeon of Other Days. Howard Dudley King.
5. Gonorrhea in Young Male Children, and Its Treatment. Walter D. Bieberbach.

1. Acute Lobar Pneumonia.—F. C. Shattuck and C. H. Lawrence refer to an analysis of 1000 consecutive cases of lobar pneumonia treated at the Massachusetts General Hospital from 1822 to 1889, made by Coolidge and Townsend, and say that the present paper, comprising an analysis of all the cases treated at this hospital from 1889 to 1917, may, in comparison with the former paper, be said to represent the results of the new régime in medicine as contrasted with the old. Parenthetically it may be remarked that the contrast reflects no great credit upon modern medicine, for it has effected no improvement in the death rate, which is higher

now by far than it was at the beginning of Coolidge and Townsend's series. The following are the author's conclusions: (1) In the 4000-odd cases of lobar pneumonia treated at the Massachusetts General Hospital from 1822 to 1917 (inclusive) the mortality has gradually increased from 10 per cent in the first decade to 28 per cent. at the present time. (2) Since 1881 there has been no significant change in the death rate. (3) The number of cases classed as delicate or intemperate has been decreasing during the same period. (4) The apparent increase in complicated cases is probably due to increased accuracy of diagnosis and recording. (5) The relative number of foreign-born patients is increasing, the mortality among them diminishing. (6) The death rate among American-born patients has increased slightly, as has the mortality among men as compared to women. This may be due to a corresponding increase in vascular diseases during the period studied. (7) The mortality rate for pneumonia in the entire series has shown no permanent important change. (8) Treatment has done nothing toward diminishing the mortality from pneumonia in the past ninety-five years. Bleeding, purging, fresh air—the result has been the same. Of particular interest is the evidence offered by our figures upon the effect of alcohol. Its habitual use during health in more than moderate amounts is shown to diminish the patient's chances of recovery. But the mortality rate among those patients who were given large amounts of alcohol during their illness is no higher than among those given no alcohol and large amounts of fresh air. Our figures do not indicate that alcohol is harmful to those sick with pneumonia. They suggest that the effect of the drug varies with the conditions under which it is given, and that it is not poisonous to those who have high temperatures and are taking insufficient nourishment. (9) No change is to be expected in the results of treatment until a specific is discovered which will neutralize the toxins of the pneumococcus. (10) The results from the serum now in use are encouraging, but limited, and until its use becomes accepted the treatment of pneumonia must be that best suited to the individual. No routine treatment has been justified by its results.

8. Syphilitic Blood on the Surgeon's Fingers in the Intravenous Administration of Arsenicals. N. B. Jenkins.

6. Treatment of Painful Dysphagia in Tuberculous Laryngitis.—Robert McD. Lukens discusses this subject with special reference to nerve blocking. He says that in all cases of painful dysphagia the internal laryngeal nerve should be blocked. There are no contraindications to nerve blocking, and this procedure aids the dietetic treatment by removing or lessening dysphagia sufficiently to allow the patient to eat necessary food. More rest is obtained, due to cessation of pain from the throat, and any number of injections may be made and the patient kept in constant comfort by injecting as soon as the pain occurs. Histological examinations of injected nerves showed that the results modified the nerve trunk very little and was usually fibrosis, and in some cases numerous spaces within the bundles of the nerve fibres. Lukens urges the wider use of this method of treating painful dysphagia in tuberculous ulceration of the larynx, as it is a procedure which can be learned easily and practised by the average practitioner.

1. The Treatment of Hookworm Infection.—Samuel T. Darling, M. A. Barber, and H. P. Hacker present these data dealing with the therapeutics of oil of chenopodium and thymol, which are derived from their report to the International Health Board, Rockefeller Foundation, on the subject of the effect of hookworm infection on the working efficiency of the people of the Malay Peninsula, Java, and Fiji. The subject is of importance on account of the presence of hookworm infection among our soldiers at this present time. The work has covered a period of about two and a half years and included observations on the natives of the Malay Peninsula as well as Chinese and such East Indians as Tamils, Telegus, Malabaris, Pathans, and Sikhs. As a result of these extended experiments in treatment, these investigators have found that the half maximum dose (0.5 c.c. three times, or 1.5 c.c.) of oil of chenopodium is the treatment for recommendation as a routine vermicide. It does not have the toxic effects of the full dose, and two treatments have the very satisfactory result of removing 99 per cent. of all worms present. It has the additional advantage of a more uniform action, a greater effect on ancylostomes, and of being less unpleasant to take than thymol. Thymol shows an advantage over this half maximum dose of oil of chenopodium in that, without producing toxic effects, the 90 grains' dosage produces a better result when single treatments are compared. This advantage disappears, however when two half maximum treatments of oil of chenopodium are given. Smaller doses compare unfavorably with a single half maximum dose of oil of chenopodium. A dose as large as 90 grains of thymol, if administered indiscriminately throughout the population, would probably give rise to serious symptoms.

8. A New Diagnostic Sign in Gastric Ulcer. F. Grande Rossi.

5. Pleurisy During the Puerperium.—Gabriel Casuso describes the case of a young pregnant woman in her seventh month of gestation who had severe pains in the chest, difficult breathing, a temperature of 103°, and a swelling in the whole left side of the chest. Puncture gave exit to some pus and an operation was made, resecting about eight centimeters of the sixth, seventh, and eighth ribs. The patient recovered and was well in a month, giving birth to her child normally.

8. A New Diagnostic Sign in Gastric Ulcer.—F. Grande Rossi describes a new sign which he claims to have discovered in the diagnosis of gastric ulcer and which consists in painful reaction to pressure made at a point four centimeters to the left of the navel and in the bisecting line of the second quadrant. To obtain it, pressure should be made with one or two fingers backwards and inwards towards the spinal column, the patient being lying down and with the abdominal walls relaxed. Grande Rossi says that the sign is very constantly present in all cases and he has obtained it in over 400 cases. The intensity of the pain decreases as the patient becomes better and returns with the relapses. The sign is present even in some cases in which other classical symptoms may be absent, and he has proved it to be true in all cases by the use of other methods, as Einhorn's thread examination of

the gastric juice, and of the feces, hemorrhages, x-ray examination, etc.

7. Prophylaxis and Treatment of Tuberculosis. Emilio R. Coni.
8. Cutaneous Diseases. José E. Lopez Silvero.
9. The Treatment of Filariotic Hematuria. Gutierrez Lee.

3. Allen's Method in Cutaneous Lesions of Diabetic Origin.—Ramon Grau mentions several cases. The first was a pruriginous eczema of the prepuce in a case of diabetes of long standing, which with Allen's method was cured very rapidly. The second case, that of an elderly lady of 65, suffering from diabetes for fourteen years. She was subjected to the plan of starvation for the relief of an abundant eruption of itching macules, and was cured in three weeks. The third case was that of a lady with a necrotic zone on the left side of the chest; the starvation plan was maintained for some time after the glycosuria had disappeared, the patient making a good recovery.

6. Fibrous Cysts of the Ovaries.—E. R. de Aragón concludes that sclerous cysts of the ovaries are more frequent than was thought, and that they may occur in complications of all other genital affections. He recommends that in every case of appendicectomy and laparotomy in women the ovaries should be examined and fibrous cysts, if present, should be removed together with the appendix.

9. The Treatment of Filariotic Hematuria.—Gutierrez Lee describes eighteen cases of this affection, due to several species of the Filaria. The disease is obstinate, being quiescent in the cold climates, to reappear when the patient goes again to a warm country. The finding of the filariae in the blood is almost certain in all cases. Gutierrez Lee has cured all his cases by the use of large doses of potassium iodide, beginning with small doses, increasing every day. All fats were excluded from the diet.

On Tuberculosis (continued from Dec. 3).—E. Schloss continues to discuss his findings in the epidemic of tuberculosis occurring among the nursing infants contaminated by a phthisical nurse. He insists upon the mildness of the symptoms observed, the infection remaining absolutely latent in the majority of cases. As to diagnostic means Schloss places the tuberculin test in the first rank, after which comes radiographic examination, which, in the cases studied, revealed an enlargement of the lymph-nodes around the pulmonary hilum. The prognosis is less dark than is usually thought. In nursing infants, as in the case of adults, there are defensive powers which may overcome the infection when there are no unfavorable constitutional factors present. The writer, in passing, refers to the present increase of tuberculosis in general, which he attributes to a multiplication of bovine infections. Treatment does not appear to influence the progress of the disease, which undergoes its evolution according to the gravity of the infection and the constitutional capacity of resistance. The factors which appear to favorably influence tuberculosis in adults (air, sun, rest, etc.) seem to be valueless in tuberculosis in nursing infants. However, hygienic measures of a general nature are not without good effects.

Gouty Feet and Hands.—E. Pfeiffer refers to his former paper on "Gouty Subjects" published in the *Lancet* April 11, 1891. He studies the deformities first described by Heberden, but supposed by him to be gouty in nature. Pfeiffer publishes photographs and radiographs of some typical cases, their characteristic points residing deposit outside of the metacarpophalangeal region, which results in the formation of

a real projecting angle. The writer explains this peculiarity by a laxity of the articular ligaments and by the progressive deformity resulting from continual movement.

December 11, 1917.

The Relationship of Infectious Icterus (Weil's Disease) to Acute Yellow Atrophy of the Liver and Hepatic Cirrhosis.—C. Hart reports the case of a man who presented icterus and hemorrhages, pains in the calves and an increase in size of the liver. At autopsy Hart found a dysentery combined with Weil's disease. Microscopical examination of the liver revealed destruction of the hepatic lobules and an atrophic, degenerated aspect of the cells. There was a commencement of cirrhosis, in the form of neoformed bilious canalicules. After having remarked that such pathologic changes do not belong to the picture of dysentery, the writer admits that they are to be attributed to an infectious icterus. This case sustains Pick's opinion, namely, that following upon an acute destruction of the hepatic parenchyma, recalling an acute yellow atrophy, a cirrhotic process may arise. Hart concludes that in very rare cases a hepatic cirrhosis succeeding upon an infectious icterus should be regarded as a new pathologic process of the present war.

The Use of Sacral (Epidural) Anesthesia in the Hospitals at the Front.—Thomashke has at length come to operate all pelvic wounds and those of the lower limbs by this procedure, and has found it particularly advantageous. In the cases he reports general narcosis was given up, much to the betterment of the patients. If the technique is exact and prudently carried out, no untoward complication will ensue. The writer has performed amputations with a dose of 70 to 80 c.c. per injection, using a 1.5 per cent. solution of novocain with 0.0004 adrenalin, which assures an anesthesia of two hours' duration extending quite high up on the trunk.

Bier's Treatment of Wounds of Soft Structures and Bone.—G. Martius finds that certain wounds are bound to become fistulous, necessitating innumerable curettages and sequestrotomies. In such cases the writer has obtained good results with the method proposed by Bier, namely leveling down the borders of the wound and curettage; then closure of the cutaneous wound by some sort of impermeable membrane (thin rubber for example) held in place with collodion or surgeon's plaster. The surface around the wound is covered with zinc paste. The wound is thus protected from the air and undergoes regeneration just as if the process took place subcutaneously. The dressings are changed about every six days. The writer has observed neither elevation of temperature nor pain from the procedure. At each change of dressing a large amount of granulation tissue in full development is seen, even growing on the secretions of the wound. The ultimate result is excellent. An even cutaneous cicatrix is obtained, movable over the underlying parts. Finally, the method is a great economy for dressing material.

The Influence of Flying on the Hematology of Man, Rabbits, and Mice.—Kaulen, from his examinations, shows that the practice of aviation produces an increase of the red blood corpuscles and the percentage of hemoglobine. This phenomenon is distinctly noticeable after three months of aviation and is not due to a concentration of the blood from thickening. The leucocytes do not follow a parallel increase. The phenomenon does not occur during a single ascension. This multiplication of the red blood cells is not accompanied by the appearance of uncleaned cells, but on the other hand polychromatophiles may appear. The blood of rabbits and mice carried in the aeroplanes was found to offer similar changes to those met with in man.

Sawdust Bread and Its Digestibility.—H. Salomon

has had a bread prepared containing 10 per cent. sawdust. Given three times to a patient suffering from rheumatism and constipation and afterwards quantitatively estimated in the stools, this bread did not cause any decrease in the absorption of other foodstuffs. It is pleasant to the taste, only becoming somewhat bitter after having been kept for some time. Its effect on the constipation was very favorable, but it results from these essays that the absorptive capacity in man for this sawdust flour is far inferior to that of the dog as has been shown by Rubner. Salomon's patient eliminated about 100 per cent. of the ingested cellulose in the feces. If, therefore, this flour cannot take the place of bread, it can at least be utilized in the treatment of chronic constipation and as a preventive of constipation which is liable to occur in diabetic subjects on account of their lack of ordinary ration of diabetic bread and fruits. The writer withholds any opinion as yet relative to the question of the assimilability of sawdust flour bread prepared according to other receipts, Hoffmeister's among others.

A Short Note by E. Friedberger (à Propos of Weil's Paper on "Statistics of Cholera").—From this article it would appear that the writer has a very mediocre esteem for both antityphoid and anticholeric vaccination. He quotes his original article in the *Zeitschr. für Aertzliche Fortbildung* No. 10, 1917. E. Weil concurs in Friedberger's opinion as far as anticholeric vaccinations are concerned (*Wiener med. Woch.* Nos. 32 and 33, 1917).

Correspondenz-Blatt für Schweizer Aerzte.

January 5, 1918.

Deafmutism in Switzerland.—According to Siebenmann goiter, cretinism, idiocy, and deafmutism have long occurred side by side in some of the Swiss cantons. A census of deaf mutes has never yet been made, and the author wishes to bring one about. Even in the eighteenth century there were 200 deaf mutes in Freiburg at a very low estimate. In Aargau, in 1813, there were 104 deaf mute cretins, and in 1843 the number had increased notably. In 1798 these two cantons appealed for government aid in educating these unfortunates, and the last concerted effort in this direction, which involved the entire country, was in 1870. At this period some of the cantons showed 42, 44, 49, etc., respectively, of cretin deaf mutes for each 10,000 inhabitants, although the general European average of deafmutism was but 8. But whether the Swiss figures were confined to cretins or for some other reason not suggested it is believed that even these high percentages represented only a half of all the deaf mutes. The cretins, being already wards of the state, their deafmutism could be readily estimated. The next census should enumerate cretins, cretinoids, and all others who furnish contingents of deaf mutes. In 1914 there were in the country 15 institutes for the instruction of deaf mutes, with a total of 814 pupils. There are to-day 3 institutions for deaf mute idiots, two of which have 57 inmates (the third is of recent origin). But many of the pupils in the 15 schools have mental defect. A distinction between endemic deafmutism, which is correlated with cretinism, and outstanding forms must be made in a country like Switzerland. If 8 per cent. presumably noncretinoid is the average for Europe, and if this figure holds good for Switzerland, then an overwhelming percentage must be endemic, and variations in individual cantons due to variations of endemicity. Of noncretins the author alludes to scattered cases due to meningitis, but otherwise is silent on the subject.

Cutaneous Allergy in the Differential Diagnosis between Variola and Varicella.—Tièche, who has been a smallpox expert for many years, and claims to have discovered an allergic phenomenon before von Pirquet's day, presupposes that his readers are familiar with his methods, which he has already published. Hence his statements are not always lucid. The allergy is recognized not entirely by the appearance of the skin, but by a microscopic study of lymph or pustular contents—although details fail. The tests require controls who are free from varicella or nonspecific vesicular outbreaks. The allergic reaction is obtained as early as ten hours after the inoculation. The author alludes

here and there to his method of obtaining human serum by curetting deep lesions, also of preliminary treatment with carbonic acid snow. Nevertheless, despite the accuracy of his method, he seems to depend largely on ordinary clinical diagnosis, especially when the latter must be promptly made. The basic facts seem to be that ordinary vaccine, variola virus, humanized lymph, and rabbit lymph, cause precisely the same allergic reaction in ordinary conditions. The author finds that his own allergy is constant. Varicella lymph, on the other hand, causes no allergy on an average control subject. Whether there is allergy in a varicella subject is not made clear, but the diagnosis of varicella appears to rest on the negative result of inoculating a control which would be positive if the subject had varioloid. The author's critics claim that his method is unnecessary, while he himself admits 2 per cent. of missed diagnoses.

Nederlandsch Tijdschrift voor Geneeskunde.

January 5, 1918.

Sporotrichosis in the Dutch East Indies.—Ten Brink publishes a brief but well-illustrated article on this subject. The disease in question is readily confounded with lues or tuberculosis in certain of the external aspects. It is common, and the different incidence in different races appears to be due to differences in the mode of living. In a total of 1553 patients treated in 1913 at the skin dispensary at Weltevrede there were 53 cases of sporotrichosis; in 1914 there were 41 cases in a total of 1307; finally in the first six months of 1915 there were 65 cases in 827 patients. The totals were 159 cases in 3687 patients, or 4.3 per cent. The diagnosis is made without difficulty by the presence of the fungus, especially in culture, as described by Beuermann. Brief notes are given of numerous cases. One patient greatly resembled a syphilitic, ulcers on the lower leg resembling ulcerated gummata. The second case was also very suggestive of lues, as was also the third. In all this series the lesions were seated on the leg and foot. In a fourth case the fungus was found with no trouble in an abscess-like formation. In another series of illustrated cases tuberculosis was simulated and in a third both diseases were suggested. In a certain acute type clinical ringworm was present. Elephantiasis (Madura foot) is another manifestation of this protean dermatosis.

Familial European Chyluria.—Koopman reports an episode of this nature. A youth of 19 was admitted to the Military Hospital at Amersfoort. He complained of a pain in his back at the level of the twelfth dorsal vertebra, also headache. The backache was never absent, and his father and father's father had suffered in the same way. He presented an angina (diphtheria bacilli found) with fever of 103.5° F., and mitral insufficiency. The angina soon passed off, but the temperature remained high. The case suggested sepsis, but no cause could be found. The sudden passage of milky urine threw light on the affection, which had become a complete riddle. No filariae embryos could be found in the blood. There are now, including the author's observation, fifty-seven cases on record of European chyluria. It is held to be due not to parasites, at least as a rule, but to an anomaly of metabolism. or to the passage of chyle from the lacteals to the urinary passages through some irregular lymphatic arrangement. The author can find no record of any familial cases other than his own. But little is said in reference to other cases in the family, aside from the bare fact. But this incidence naturally raised the question of a parasitic cause, and this, as already stated, was not at all in evidence.

Malignancy of the Hypophysis and Progressive Paralysis.—Goldstein appears to have shown that an adenocarcinoma of the hypophysis acted as a factor in lighting up metasyphilis. The spirochetes, doubtless long present in the cortex, were not roused to virulence until the tissues had reacted to the presence of the intracranial tumor. Or the latter may have acted indirectly; destruction of the hypophysis may have deranged the endocrine organs and through them the metabolism.—*Gaceta Médica Catalana*.

Book Reviews.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles, etc. Edited by H. R. M. LANDIS. VOLUME III. Twenty-seventh Series. 1917. Price, \$2. Philadelphia and London: J. B. Lippincott Co.

MANY of the contributors to this volume stand at the head of the profession, and this is true especially of the clinical lectures. Material of this sort is easily obtained, for it is only necessary to take notes on the lectures by distinguished clinicians, which would be delivered irrespective of the demands of the book. De Schweinitz states that almost every case of inflammation of the uveal tract is septic, very many being traceable to dental foci. Beifeld makes venesection the rational treatment of polycythemia. Christian distinguishes between disordered renal function and nephritis. We may see in enlarged prostate or pernicious anemia practically the same chart as in actual nephritis. Grulee would abstain from catharsis in infantile constipation and depend upon diet and mechanical agencies like paraffin oil and glycerin suppositories.

The articles written especially for the clinics, while of a high class, lack some of the interesting quality of the clinical lectures. The subject of the treatment of hyper- and hypotension, by Satterthwaite, is, of course, somewhat trite, but the eminence of the author makes it worthy of a careful perusal. The article on pseudochylous ascites, by Weber of London, consists chiefly of case histories. Fondé of Mobile injected enormous quantities of antiphtheritic serum into the peritoneal cavity in an exceptionally malignant case of diphtheria. On the sixth day the quantity injected was 344,000 units, and on the seventh day 560,000 units, etc. Life was prolonged until the tenth day. The total number of units injected was 2,679,000, beginning on the third day. Sharpe's results in the surgical treatment of spastic paraplegia by cerebral decompression have appeared before. Steele's case of true hermaphroditism in a negro, confirmed by operation and the microscope, seems genuine. Psychically the subject is a woman, and menstruation occurs regularly. Maleness is shown only in the musculature, pelvis, and pubic hair. There is also a pseudopenis, while the vagina is rudimentary. Sexually the subject is neither male nor female, or at least had never had true coitus in either capacity.

SURGERY AND DISEASES OF THE MOUTH AND JAWS. A Practical Treatise on the Surgery and Diseases of the Mouth and Allied Structures. By VILRAY PAPIN BLAIR, A.M., M.D., F.A.C.S., Professor of Oral Surgery in the Washington University Dental School, and Associate in Surgery in the Washington University Medical School. Third Edition. Revised so as to incorporate the Latest War Data Concerning Gunshot Injuries of the Face and Jaws. Compiled by the Section of Surgery of the Head, Subsection of Plastic and Oral Surgery, Office of the Surgeon-General of the Army, Washington, D. C. Octavo of 733 pages, with 460 illustrations. Price, \$6. St. Louis: C. V. Mosby Company, 1917.

THE present revision of the work resulted from the apparent need for an authoritative treatise on the diseases and injuries of the mouth, face, and jaws that would embody the results of observation of great numbers of these injuries and the best methods of their treatment, as demonstrated by experience during the past three years of war. Owing to the necessity for haste in providing a suitable textbook on these subjects for use in training members of the Medical Reserve Corps, it was considered best to take the textbook that seemed to furnish the best foundation and revise those sections that were necessary in order to meet the requirements of the situation. Accordingly, this revision of Blair's book was made with the help and under the supervision of the Surgeon-General's Office.

The book is not completely revised—indeed, the author takes pains to indicate this clearly in his preface. What he does say is that the revision is mostly confined to the parts related to injury and sepsis and their treatment. He also says that the subject of peridental infections has been rewritten by Dr. Arthur D. Black;

that the chapter on local anesthesia has been revised by the original author, and that on general anesthesia by Dr. Ellis Fischel; and that because of insufficient time the other chapters not referred to in this preface were not revised.

Even before this revision this was an excellent work, and it has, of course, been made of still greater value through the incorporation of material bearing upon the treatment of conditions incident to war. As it now stands, it is undoubtedly one of the best and most practical treatises devoted to this special field of surgery.

THE MASTERY OF NERVOUSNESS, BASED UPON SELF-RE-EDUCATION. By ROBERT S. CARROLL, M.D., Medical Director, Highland Hospital, Asheville, N. C. Price, \$2.00 net. New York: The Macmillan Co., 1917.

THE chief fault of this book is the failure to evaluate the neurotic according to the modern viewpoint—the tendency to regard solely poor hygiene, economic struggles, and modern intensity in general, together with the growing prevalence of the use of stimulants and narcotics, as the bed from which neurotics spring. It is quite conceivable that a book of this kind, addressed to a lay audience, may do some good by inculcating right methods of living in some whose symptoms have their origin only in such causes, but it can hardly be regarded as a complete study of "nervousness."

DISEASES OF THE SKIN: THEIR PATHOLOGY AND TREATMENT. By MILTON B. HARTZELL, A.M., M.D., LL.D. 51 Colored Plates and 242 Cuts in the Text. Price, \$7.00. Philadelphia and London: J. B. Lippincott Company, 1917.

IN this work Professor Hartzell has given a most excellent presentation of what is known concerning diseases of the skin—that is, so far as their pathology and treatment are concerned. The facts set down are founded mainly upon the author's own experience as a worker and teacher of dermatology for more than twenty-five years. In addition, in order to render the book comprehensive, as a practical guide for the general practitioner, and as a useful work of reference for the student of medicine, the standard treatises of American and European authors have been liberally drawn upon, and especially is the author indebted to La Pratique Dermatologique and Ureck's Handbuch der Hautkrankheiten. Particular attention has been paid to the subjects of etiology and pathology, and all the remedies and methods of treatment of approved value have been included, and especially those which the author's own experience has led him to rely on. Emphasis is laid upon the influence that food and clothing exert in predisposing to and causing diseases of the skin. The work is profusely and well illustrated, many of the illustrations having been reproduced from Professor Hartzell's own collection of photographs. The work is particularly well adapted for reference by the general practitioner, as the various forms and diverse symptoms of skin diseases are described concisely and clearly. While no points of real importance are omitted, over elaboration is avoided. The book is good from all points of view.

PAIN AND PLEASURE. By HENRY THOMAS MOORE, Ph.D., Assistant Professor of Psychology, Dartmouth College. OUR SENSES SERIES—GEORGE VAN N. DEARBORN, Editor. New York: Moffat, Yard and Co., 1917.

THIS little book is one of a uniform set which has for its object the endeavor to make accessible to the lay public certain elementary psychological and physiological facts. The present volume is more successful than some others in the series which the reviewer has seen. Professor Moore has presented in a clear manner the fundamentals of his subject. He appears to have selected with great judgment his elementary facts and, where facts are disputed, he has touched on both sides of the question. As indicative of his breadth of outlook it may be mentioned that he even alludes to Freud, and not unfavorably. The book is one which the physician can recommend to the youth who is anxious to learn, or to the adult who, after an early life of ceaseless toil, wishes to understand something of the basic emotions which move the world.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting Held December 7, 1917.

Dr. JOHN DOUGLAS IN THE CHAIR.

To illustrate a New Method of Treating Greenstick Fracture of the Forearm.—Dr. WESLEY GROVE VINCENT presented this patient, a little boy seventeen months of age, who came to his clinic in the Post-Graduate Dispensary on February 2, 1917, with a history of having fallen and injured his left forearm three weeks previously. From the pronounced bowing it was evident even upon casual inspection that there was a greenstick fracture of both bones of the forearm. This diagnosis was corroborated by the x-ray plate. The callus was still soft enough so that the arm could be partly straightened, but there was a marked convexity of the posterior surface, which tended to become more pronounced as soon as the corrective force ceased. In view of Taylor's success with elastic traction in cases of Volkmann's contracture, the speaker decided to employ that principle in dealing with this case. A padded wooden splint reaching from the elbow to the palm was applied to the anterior surface of the forearm and held in position by adhesive plaster straps. A fairly thick gauze pad, about 1½ inches square and enclosing a bit of wooden splint, was placed over the prominent point on the back of the forearm, and a rubber band one-eighth of an inch wide was slipped over the hand and arm and held in position over the gauze pad by a strip of adhesive plaster. The rubber band was used under moderate tension and caused no interference with circulation below that point. A gauze bandage, snug but not compressive, was then applied from the palm to the elbow. A week later the bowing was found to have markedly decreased; but as the elastic band had been allowed to touch the skin at each border of the arm, the skin had been partially cut through at each of these situations. This mistake in technique was corrected in subsequent dressings in this and other cases by making the splint on the concave surface somewhat wider than the arm and passing a broad strip of adhesive plaster rather loosely around the arm over the splint and gauze pad which had been placed at the point of greatest convexity; the rubber band was then adjusted over this and held in position by short adhesive strips placed vertically both anteriorly and posteriorly. Since adopting this technic there had been no excoriation of the skin. Within three weeks all trace of bowing had permanently disappeared. The speaker had since used this device in other cases of greenstick fractures of one or both bones, always with the same happy result. He felt inclined to believe that if elastic traction was used in this way from the outset in greenstick fractures of the forearm it would rarely if ever be necessary to complete the fracture in order to insure a straight arm. The proper technique in the straightening process seemed to be absolutely painless.

Congenital Umbilical Fistula. — Dr. VINCENT also presented this patient. He stated that the patient, a girl 6 years of age, was admitted to the Babies' Ward of the New York Post-Graduate Hospital, on August 23, 1917. She gave a history of a persistent discharge from the navel since birth. A short time ago the fistulous tract became infected, and this resulted in an abscess which ruptured the morning of her admission to the hospital with the discharge of a small amount of seropurulent material. Examination revealed a small fistulous opening which admitted a probe to the extent of about three-quarters of an inch. The probe passed backward and downward. The tissues were infiltrated and sensitive to the touch over a small area to the right and below the umbilicus. As the discharge had been clear and watery or mucoid in character, never feculent or urinous, it seemed certain that its source was a Meckel's diverticulum or urachus, the canal of which had been obliterated at some point between the umbilicus and the intestine or bladder. After about two weeks spent in ineffectual efforts to overcome the infection, an incision was made a little to the right of the median line and the peritoneum was opened. The umbilical re-

gion was everted and an almond-shaped cyst about ¾ by 1½ inches in size was found beneath the umbilicus and running downward toward the bladder. There was no evidence that the cyst had ever been connected with the intestine and the diagnosis of urachal cyst seemed positively confirmed. The cyst wall was intimately adherent to the peritoneum, so the umbilicus, cyst, and palpable indurated tissues were excised *en bloc*. The abdominal wall was closed in layers and a rubber drain inserted. Convalescence was uneventful except for a rather protracted superficial suppuration. The pathologist reported an enteric cyst, stating that the lining membrane consisted of villi covered with columnar epithelium. Beneath the villi were the acini of glands closely resembling Brunner's. The picture was that of a diverticulum of the small intestine. The atypical structure of the coiled glands suggested a fetal endoderm.

Showing Result Five Years after Excision of the Shoulder for Tuberculosis.—Dr. VINCENT presented a third patient, a woman, who came under his care at the Post-Graduate Hospital five years ago, at the age of 28 years. Her family and previous history were not important. About a year and one-half before her admission to the hospital, while lifting something, she experienced pain in the right shoulder. This pain resolved itself into a subacute aching sensation about the tissues of the shoulder and articulation. During the six weeks previous to her admission the distress had increased and all movements of the joint were very painful. During the year and a half that she suffered from pain she had run the gamut of treatments for rheumatism. She had visited divers private physicians and dispensaries and various diagnoses had been made, rheumatism being the favorite and neuritis a bad second. She had finally been sent to the neurological department of the Post-Graduate Hospital, from which department she had been referred to the speaker. A diagnosis of tuberculous osteoarthritis was made, and this was confirmed by the x-ray plates. The speaker did a subperiosteal resection of the head and neck of the humerus by Ollier's method. As much as possible of the tuberculous synovial membrane was dissected and curetted out and the entire cavity flooded with 95 per cent carbolic acid. This was allowed to act for several minutes before being neutralized by 95 per cent alcohol. Two iodoform gauze drains were inserted and the shoulder immobilized for about ten days. The sinuses ultimately closed after being distended a number of times with 95 per cent carbolic acid, the excess of which was allowed to flow out and neutralized only at the skin surfaces with alcohol, by a gauze dressing soaked in 95 per cent alcohol. Though the woman was pregnant at the time, the operation caused no interference with the progress of the pregnancy. Long before she was discharged from the dispensary she did her own housework and recently had been working in a tobacco factory in addition. She had never had any reopening of the sinuses or further involvement. Dr. Vincent exhibited an x-ray plate showing the bony condition nearly two years after the operation. There were three points to which attention was directed in connection with this case: 1. This patient was long mistreated under the wrong diagnosis of rheumatism—an all too common error with both acute and chronic form of osteomyelitis. 2. Excellent x-ray plates failed to show the entire extent of the lesion. 3. By doing the resection of the tuberculous humeral head by the subperiosteal method, not only was the danger of severing the circumflex nerve minimized, but no vessels of importance were encountered and no muscles or tendons were cut across which must be united later through a contaminated tuberculous field.

Dr. FORBES R. MCCREERY described a case of umbilical fistula somewhat similar to the one reported by Dr. Vincent. He said this patient was a woman, 36 years of age, who had never had a discharge from the navel until at the time he saw her, in May, 1913. She gave a history of having had a great deal of abdominal pain for about six days, and on the morning that she came to consult him she had had a discharge from the umbilicus; there was some rigidity and tenderness and a polyp presented. He probed the canal of the fistula and found it about one and one-half inches in depth. About one-half a dram of pus escaped followed by about a dram of cheesy material like the contents of a wen.

He then curetted the epithelial layer of the canal in order to obliterate the cyst. He packed it first with one per cent. formalin; after two days he curetted it again and swabbed it out with 50 per cent. iodine, and two days later with Churchill's iodine. The wound was then closed up, the polyps having disappeared. He thought this was a cyst of the omphalo-mesenteric duct. If he had seen the patient before the discharge had begun, he would probably have advised operation but as it was he did not. He curetted carefully so as not to perforate the wall and only destroyed the epithelial lining. The probe had entered at an angle of about 45 degrees with the anterior abdominal wall, and the cyst obviously lay within the latter. He saw the patient in July, 1917, and there had been no recurrence.

Dr. DOUGLAS asked Dr. Vincent how he accounted for the discrepancy between the apparent condition at operation and the pathologist's report.

Dr. VINCENT, in reply to the question as to how he accounted for the pathological condition in the second case, said he had been completely nonplused when he received the pathologist's report, because the condition was distinctly below the umbilicus; there was no connection with the intestine and at the operating table it seemed clearly a case of urachal cyst. He was disposed to doubt the correctness of the report until he went to the pathologist and saw the sections of the specimen which showed definitely intestinal elements, including sections of Brunner's glands. The pathologist herself had been in doubt and had taken the specimen to Dr. Ewing, who said it was an enteric cyst. Dr. Ewing's theory was that some enteric cells had been pinched off early in the embryonal stage and that this cyst was the result. The patient had been treated for nearly six years and the condition never could have been cured except by excision.

Uretero-Vesical Anastomosis (Two Cases) with Moving-Picture Demonstration of Operation.—Dr. H. DAWSON FURNISS made this presentation. He stated that the first patient gave a history of having had a miscarriage in 1911, at which time she was curetted. About fourteen days later an abdominal operation became necessary, and then within seven months she had two other abdominal operations. Following this she had intense pain in the right side of the abdomen and back, which was more or less continuous. She finally came to the gynecological department of the Post-Graduate Hospital, where it was found that she had a slight obstruction to the passage of a ureteral catheter about an inch above the orifice of the ureter. A Pyelo-ureterograph showed a dilated ureter with obstruction at the lower end. A ureteral vesical anastomosis was performed such as was illustrated by the pictures. It was now 2½ years since the operation was performed and there was no diminution in the function of the kidney on the side of the anastomosis as was demonstrated by the indigo-carmin and phenolsulphonaphthalein tests. The patient has been relieved of her symptoms. The idea was prevalent that after a uretero-vesical anastomosis there was a diminution of kidney function on the side of the anastomosis due to contraction of the ureter. The second case was that of a girl who for two years had suffered from attacks of pain in the left lumbar region. The first attacks lasted five or six hours and occurred at intervals of about four months. The attacks then became more severe and the intervals shorter. Examination showed the left ureter edematous. The urine was negative for tuberculosis both by microscopical examination and animal inoculation. Colon bacilli were found. It was impossible to catheterize the left ureter at all. After the intravenous injection of indigo-carmin, none came through in 30 minutes on the left side, but in four minutes on the right side. A uretero-vesical anastomosis was done on March 25, and the indigo-carmin test six weeks later showed that the dye came through in six minutes, which was only a slightly less time than on the right side. This patient was up and about on the twelfth day and was absolutely free from trouble. Dr. Furniss said that in this operation he made no attempt to split the ureter and to suture the flattened ends to the bladder wall. This did not seem to be necessary as the tendency to obstruction was not at the end but where the ureter entered the bladder. It was not difficult to perform the anastomosis as the ureters were usually thickened and dilated where there

had been an obstruction. Dr. Furniss then gave a moving-picture demonstration of the operation.

Dr. DOUGLAS asked Dr. Furniss whether he bored two holes in the bladder in order to get the ureter and draw the end into the bladder.

Dr. FURNISS replied that he did puncture the bladder by lifting up a double fold and passing artery forceps through both folds from before backward. The ureter was then pulled through both folds and sutured to the posterior fold. By releasing the end of the ureter it dropped back into the bladder and the opening in the anterior wall was then closed. Dr. Furniss explained the technic of this procedure in detail and said it was much cleaner than going through the urethra and was less likely to be followed by infection. He drew the ureter into the bladder one-quarter or one-eighth of an inch and in the course of two or three months the projecting end of the ureter had disappeared. In attaching the ureter he just sewed the musculature of the bladder to the ureter. In dissecting the ureter one should not dissect it from its peritoneal attachments any further than was necessary and then the ureter should be inserted into the bladder up to its peritoneal attachment.

Dr. DOUGLAS asked how far above the bladder an anastomosis could be made.

Dr. FURNISS replied that if the stricture was more than two inches above the opening of the ureter into the bladder it was very difficult to make an anastomosis and if there was tension on the ureter the operation was likely to result in failure.

Carcinoma of the Sigmoid with Resection.—Dr. WALTER C. CRAMP presented this patient who was admitted to Bellevue Hospital on December 10, 1916, suffering from intestinal obstruction. Rectal and abdominal examination failed to reveal any cause for the obstruction. The woman was 56 years of age, and according to the history she gave had been suffering for six months with increasing constipation. There was a tumor about the size of an apple in the lower portion of the sigmoid. Because of fecal vomiting and the typical symptoms of intestinal obstruction, a colostomy was performed on December 27 and later the portion of the sigmoid that was involved was resected and the glands in the vicinity removed. In doing the resection a large rectal tube was passed upward through anus and sutured to the upper segment which was pulled down into the lower segment, thus invaginating the proximal into the distal portion of the sigmoid and these were sutured in place, using two layers of chromic gut and one of Pagenstetter suture. The tube came out on the seventh day with slight traction. There was an infection of the original abdominal wound and on February 9 this colostomy wound was closed. On March 16 the patient was discharged from the hospital. Her weight, which was 112 pounds at the time of the operation, had increased to 147 pounds. She had had no symptoms of obstruction since the operation and felt perfectly well. A careful abdominal and proctoscopic examination revealed no signs of recurrence. There was a slight ventral hernia subsequent to the resection operation. The pathologist reported that the tumor removed was an adenocarcinoma.

The Biological and Clinical Evidence of the Therapeutic Value of Radium and Roentgen Rays in Cancer.—Dr. ISAAC LEVIN presented the results of an experimental study on the influence of the x-rays on the development of the crown gall. The latter was an infectious disease of plants very analogous in many respects to human cancer which could be induced artificially by inoculating the plants with a pure culture of *Bacterium tumefaciens* described by E. F. Smith of Washington. The plants were x-rayed by modern methods using hard rays which did not injure the normal plants, as preliminary experiments had shown. While in the control plants the inoculation was invariably followed by the development of a large tumor, so-called "crown gall," the plants which were x-rayed subsequently to the inoculation either developed no growth at all or only a slight swelling at the place of inoculation. The experiments show that x-rays of correctly selected quality and quantity might arrest the growth of a malignant tumor without injuring the normal parts of the plant. Another interesting observation found in the course of these experiments was the fact that the microscopical

study of the minute nodules on the x-rayed plants showed the identical morphological picture that was obtained in a full-grown crown gall. These latter results were identical with the results of radium and x-ray treatment in a series of cases of carcinoma presented in detail by the writer in which a clinical arrest of the disease was accompanied by a complete absence of morphological changes. The result of this experimental and clinical study proved that the morphological appearance of radiated tumor tissue was not an absolute criterion of the therapeutic effect produced by the action of the rays on the tumor. The biological or clinical evidence of the arrest of growth or diminution of the size of the tumor was of undoubted value. The complete destruction of the tumor cells was the most perfect result and took place in the majority of cases even in large tumor masses. On the other hand negative morphological changes did not preclude the possibility that the tumor was influenced by the rays. Radiated and nonradiated carcinoma tissue might have the same microscopic appearance and still the former tissue was sterilized and might have lost, to a great extent, its power of proliferation and consequently its clinical malignancy. The practical conclusion to be derived from this investigation was the following: It was advisable to radiate malignant tumors not only after an operation but in a certain class of cases also before an operation so as to sterilize and inhibit the proliferation of the cancer cells which might be left behind or even transplanted elsewhere in the course of an operation. Such a procedure did not prolong appreciably the time preparatory to an operation and presented no danger to the patient. The fear expressed by some workers that the raying might occasionally irritate and increase the rate of growth of the tumor was unfounded. There was no biological evidence of such irritating action of the rays on any cell. The result was always an inhibition. Clinically, the author has seen in a series of cases of carcinoma of the rectum that the same sudden increase in the rate of growth of a malignant tumor might follow a radical operation. In either case the sudden increase of malignancy of the tumor was simply a coincidence and was not due to any method of treatment.

Dr. I. S. FEINBERG called attention to the fact that Dr. Levin had failed to mention what particular tube he used or what type of ray filter. He had been interested in this work for some years and a matter that had seemed of importance to him was the changes wrought in the blood elements, as for instance in the red blood cells, the white blood cells, the erythrocytes, etc. In one patient with a degenerating fibroid that showed evidence of malignancy, the red blood cells numbered 2,500,000 and the hemoglobin content was 30 per cent. From the blood picture it was thought the patient had a pernicious anemia. For six months she was treated weekly with radium using a soft tube and under this treatment the blood content increased to 5,000,000 red cells and 80 per cent. hemoglobin. There seemed during this time to be no marked change in the size of the fibroid but there was marked improvement in the circulation; edema of the legs and puffiness about the eyes disappeared under the treatment, and the patient made an uneventful recovery after operation and had remained perfectly well since, her weight increasing from 102 to 140 pounds. It would be interesting to hear Dr. Levin's experience in respect to the improvement in the blood elements.

Dr. WILLY MEYER said it would be untimely before an audience such as this to speak of the effect of the x-ray in cancer because they all now made it a rule after operation for carcinoma to have the x-ray or radium used and did not consider the surgical treatment complete without it. Such a presentation as they had listened to tonight showed the effect of the x-rays on cancer and all who had worked with radium had proved for themselves that these rays had a distinct influence upon growths. It stood to reason that if the microscopical work had left no trace of a growth they must believe that the microscopical elements were also destroyed. One point he especially wished to emphasize was that x-ray or radium treatment should not be given before operation and it should not be omitted after operation for a malignant growth. Dr. Meyer reiterated his belief that carcinoma was an infectious disease; it was originally a local disease and if it was recognized and re-

moved early before it reached the lymph glands it could be cured. If it passed the lymph glands and entered the blood then it caused a metastatic growth and could not be cured by surgery. In fact cancer acted very much like any other infection, and he felt sure that Irwin Smith was on the right track. Dr. Meyer related an instance of an infiltrated epithelioma of the cheek which was apparently cured by radium and said that when one saw one such a wonderful result he did not need more to convince him of the value of radium in the treatment of such epithelioma of the face.

Dr. BARNET JOSEPH said that perhaps as a worker with Dr. Levin he might add that they had found radiotherapy especially effective in three conditions which hitherto had been considered quite irremediable; in the treatment of these three conditions the rays had taken a place almost comparable to quinine in malaria or salvarsan in syphilis. The conditions he referred to were, first, lymphosarcoma; Dr. Howard Kelly had recently shown in this very room a number of cases of lymphosarcoma which demonstrated the marked value of radiotherapeutic treatment. It was certainly marvelous to see how lymphosarcoma melted away under radium. In one instance of lymphosarcoma of large size, Dr. Levin applied radium and at the end of ten hours the tumor had diminished one-third in size, and by the end of six months there was absolutely no sign of the disease present. This patient looked better and the hemoglobin had gone up from 60 to 90 per cent. A second condition in which radiotherapy was effective was in leucemia, especially splenic leucemia. He at present recalled one case in which the red blood count had come down remarkably and there was a corresponding increase in the white blood count. In another patient having leucemia and practically moribund, a marked improvement was observed within twenty-four hours after the x-ray treatment. This patient was now up and about though it was too soon to say whether the cure would be permanent. A third condition which was amenable to radiotherapy was epithelioma of the face. In this condition surgery was disfiguring and sometimes very disappointing. Under radium treatment these epitheliomata were seen to disappear so that scarcely a scar would remain. These three conditions might be classed as a group of diseases which radium alone would relieve.

Dr. ARTHUR F. HOLDING said that the essayist should be congratulated upon his presentation of the comparative biology of plant and animal cancer and upon his excellent illustrations. Dr. Joseph had just called attention to three diseases which were readily affected by radioactivity. A study of haematoxylin-eosin sections of the diseased tissues in each of these diseases shows a field blue with nuclei. The nuclei took the blue stain, and the fact that the slides were so blue meant that nuclei predominated over the cells in lymphosarcoma and in the enlarged glands of Hodgkin's disease and leucemia. This would likewise be found true in tuberculous glands and epitheliomas of the face when of the basal type. On the other hand, in cases of squamous epithelioma, one did not get as good results with the rays as in the above mentioned conditions; if one remembered that the nuclei in squamous cell epithelioma did not predominate, but that the cell substance predominated, it helped to explain why one got better results in conditions in which the nuclei predominated. Dr. Holding said they also had very amazing results from the application of the rays to ovarian and testicular tumor cells; we all know that these cells had very active nuclei. It would seem from these observations that in any tumor in which the nuclei predominated over the cell substance and which was related in nature to embryonal tissue, they could expect to get wonderful results with the rays. In short, they got the best results in tumors where the largest and most prominent nuclei were found; this would seem to classify cases in respect to their response to radioactivity according to their histo-pathology. It had been his experience that in employing this treatment at first one got very wonderful results and astonishing clinical cures and became very enthusiastic over the treatment; then, if he followed these cases he found that after six to eighteen months, one began to see recurrences and after five or six years' experience his enthusiasm almost reached the vanishing point. However, one did get good results in the classes

of tumors referred to, but in lymphosarcoma, Hodgkin's disease, leucemia, and embryonal carcinomas one did get recurrences and the patient died. While radium and x-rays produced results in these cases they were not permanent. The methods of administration of these agents would have to be greatly improved before they could be pronounced a cure.

Dr. JOHN DOUGLAS asked Dr. Levin in what proportion of the cases treated by radiotherapy he obtained favorable results. He said he did not want to be pessimistic, but his experience did not match with that reported by some of those who were using radiotherapy. He had seen wonderful results in lymphosarcoma, but the patients came back with recurrences and sooner or later died. One of the speakers had spoken of seeing Hodgkin's disease simply melt away under this treatment, but it came back again, and he had seen the same thing happen in leucemia. Dr. Meyer had spoken of the results that Dr. Pfahler had obtained in epithelioma of the lip; these are squamous epitheliomata and this was a condition in which the cells were said not to be easily affected by radiotherapy. Dr. Douglas called attention to those cases of pernicious anemia which go through a crisis and improve for a time without even radiotherapy. Dr. Joseph had spoken of cures in melanotic sarcoma. In this connection it might be recalled that Dr. Mathews had shown a case, before the New York Surgical Society last year, of melanotic sarcoma which was so far advanced apparently that it did not seem worth while to attempt to remove the whole growth, yet that man was still alive several years later. Scirrhus carcinoma of the breast had also been mentioned by Dr. Levin as a condition he had treated by radiotherapy, and although not cured was prevented from progressing. It was well known that this was a form of carcinoma of slow growth and might persist for years with very little change. Dr. Eisenbrey, formerly Surgical Pathologist of St. Luke's Hospital, had had the opportunity of examining a large number of cases of carcinoma of the cervix previously treated by radium in which a hysterectomy was done later, and he expressed the opinion that he was absolutely positive that the radium had caused irritation about the edges of the tumor, and stimulated its growth, and his conclusions were based on a study of many specimens removed at operation. Dr. Douglas said he would also like to ask Dr. Levin how he reconciled his theories with the results of Dr. Murphy's experiments. Dr. Murphy had last winter read a paper before the Academy in which he gave the results of the treatment of mouse tumors by the x-ray and radium. He removed the tumor, then treated it with the x-ray and replaced it in the body of the mouse. These tumors continued to grow. He then, in another series, removed the tumor, treated the mouse from which the tumor had been removed with the x-ray and replaced the tumor. These tumors in many instances failed to grow. He explained these phenomena by the theory that the x-ray caused a lymphocytosis which inhibited the growth of the tumor. He also stated that further radiation would lessen this inhibitory action.

Dr. LEVIN, in closing, said it would take too long to answer the question with reference to the kind of tubes and type of ray filters used, but he would be glad to explain the technique and to show the clinical results of this treatment to any one who would visit his laboratory. In reply to the question as to whether there was such a thing as a cancer cell, he said that the whole problem of cancer on which he had been working for 30 years was based upon the study of the difference between the normal somatic and the tumor cell. He agreed with Dr. Willy Meyer that clinically cancer might appear to be analogous to an infectious disease, but from the standpoint of a pathologist the two classes of diseases differed widely. Moreover were it proven that cancer was an infectious disease, the discovery would not necessarily have been an aid in the therapy of cancer. A specific remedy for tuberculosis was still not discovered though the etiological agent—the tubercle bacillus—was known for a long time. Dr. Meyer misunderstood the author's standpoint on preoperative radiation. It was not meant for cases clearly amenable to a radical operation, but for borderline cases. There were reported a great many cases of carcinoma of the uterus for instance which only became operable after a preliminary radiation. He has seen recently cases

of carcinoma of the rectum which were operated upon three and four times within a few weeks. In such cases a preliminary radiation would have certainly diminished the number of operations. In reply to the question of Dr. Douglas he stated that statistical studies which he reported recently showed that the treatment of inoperable cases was followed by 6.7 per cent. of cures in hospital cases and in about 11 per cent. in private cases, which compared favorably with surgery, which shows 12 per cent. of cures in all cases of cancer, many of which were more favorable than those submitted to radiation. Moreover, as stated by Dr. Joseph, a large lymphosarcoma which had broken through the capsule of the gland and grown into the surrounding tissue was dissolved by radium without leaving a vestige of the tumor, and at the same time the skin or the subjacent normal tissue over which the tube of radium was placed did not show the slightest abnormality. Such a result presented the most wonderful phenomena ever obtained in therapeutics and was a great deal more convincing to a student and investigator in biology of cancer than all the clinical statistics.

Stated Meeting, Held January 4, 1918.

DR. JOHN DOUGLAS IN THE CHAIR.

Election of Officers.—The officers of the Section elected to serve for 1918 are: *Chairman*, Dr. Seth M. Miliken; *Secretary*, Dr. Seward Erdman.

Double Transverse Incision.—Dr. ALLEN O. WHIPPLE presented two cases. CASE I.—This patient was a woman, 45 years of age, admitted to the Presbyterian Hospital on February 26. She gave a history of pain during the last two weeks, localized in the right upper quadrant, nausea, and vomiting. There was marked tenderness in the gallbladder region, increasing in severity. There was no jaundice, no hematemesis, and no urinary symptoms. Physical examination showed moderate rigidity and a mass was felt just below the costal margin. The temperature was 103° F.; white blood corpuscles 20,000, and polymorphonuclears 83 per cent. The patient was observed for two days, when her condition improved and it was considered that she had passed the acute stage of her attack and was suitable for a cholecystectomy. At the first operation a transverse incision was made. The gallbladder was found markedly inflamed, surrounded by omentum, and contained about 50 cm. of yellow pus. No stones were found. Because of the great vascularity of the adhesions about the cystic duct and absence of gallstones a cystostomy was done. The patient made a smooth recovery. Cultures of the pus showed the presence of the *B. coli*. Three months later the patient complained of pain in the right upper quadrant and soreness. Two weeks later she had three violent attacks of pain with increasing tenderness over the gallbladder, with a red softened area in the center of the scar. The pain was so severe that she asked that the gallbladder be removed. A second operation was performed on June 2, 1917, a transverse incision, including the scar, being made. A probe was introduced through a sinus opening which had developed and this passed to the gallbladder. The gallbladder was adherent to the anterior abdominal wall. It was markedly shrunken, thickened, and the cystic duct was occluded. It contained mucopurulent material and fifteen faceted calcium, cholesterol stones, averaging ½ cm. in diameter. No stones were felt in the common duct. The pancreas was soft. Cholecystectomy was done following the separate ligation of the cystic duct and vessels. A cigarette drain was placed to the bottom of Morrison's pouch. Cultures of the mucopurulent material showed the presence of the *B. coli*. Owing to a misunderstanding of orders the drain was removed on the second day. This was followed by a subhepatic abscess and a severe cellulitis of the abdominal wall. The subhepatic abscess was drained with a tube but the cellulitis of the abdominal wall was not controlled until Dakin's solution was used. Six weeks after the operation there were two small chronic stitch sinuses. There was no hernia. The patient's digestive disturbances and the pain and tenderness in the right upper quadrant had disappeared.

CASE II.—This patient, a man 33 years of age, was admitted to the Presbyterian Hospital on July 4, 1916. He gave a history of having had five attacks, at irregular intervals, of epigastric pain radiating to the right shoulder, vomiting, and tenderness in the right upper quadrant. The pain was at no time related to his meals. He had no hunger pain. Bismuth x-rays of the stomach were unsatisfactory. A diagnosis of cholecystitis and cholelithiasis was made. At operation a transverse incision was made. The gallbladder was found adherent to a mass below it and to the outer side of the duodenum, but it was not a primary lesion. No stones were found in the gallbladder. A retrocecal mass pointing up between the right margin of the duodenum and hepatic flexure of the colon was found. This proved to be an abscess. The wall of the duodenum posteriorly was so intimately adherent to the abscess wall that it was considered to be an abscess following a small perforation of a duodenal ulcer. As the patient was taking the anesthetic badly more than inversion of the ulcer and the institution of drainage was deemed unwise. The drain was passed into the abscess through a lateral stab wound. After inverting the ulcer with a Pagenstecher purse-string suture, the abdominal wall was sutured without drainage. Convalescence was unusually smooth. The patient was discharged three weeks after the operation. Two weeks later, while in the country, the patient had a similar attack which was diagnosed as appendicitis. At operation nothing but dense adhesions were found. The appendix was not located. During the following nine months the patient had recurring attacks of typical duodenal ulcer pain two or three hours after eating, which were relieved by small amounts of food. In April, 1917, he had an attack similar to the one he had on his first admission to the Presbyterian Hospital. Another operation was advised. A transverse incision was made below the first, through both recti muscles. An indurated mass was felt to the right of the duodenum. A posterior short-loop gastroenterostomy was done. Before closing the abdomen a fenestrated rubber tube was passed through a lateral stab wound into the abscess behind the colon and to the outer side of the duodenum. No perforation was found. The cultures were sterile. The post-operative course was smooth, the abdominal wound healing by primary union. The patient had experienced complete relief of his symptoms though he adhered to a careful diet, no fried, greasy or highly seasoned foods, no pastry, and no coffee or alcohol being allowed. The x-ray showed the stoma between the stomach and jejunum freely patent. There was no duodenal retention.

Dr. DOUGLAS said that Dr. Moschowitz had used the transverse incision, but he understood that after having had two or three cases go wrong he abandoned it.

Dr. WHIPPLE replied that Dr. Moschowitz was still using the transverse incision. In reference to the questions as to whether these transverse incisions separated and as to the danger of hemorrhage, he had operated through a transverse incision on some 62 cases and in no instance had there been a separation of the wound. He had had one hernia in the 63 cases. It had the advantage that it could be closed in a short time using the chain stitch. If the incision was made through the rectus and down through the deep epigastric these vessels were ligated and one did not have hemorrhage and the muscle sheaths did not retract. He used chromic gut mattress sutures in the muscle and plain gut for the superficial sutures. It was much easier to close such a transverse incision than a linear incision.

Pilonidal Cyst (Two Cases).—Dr. FRANK C. YEOMANS reported these cases. He stated that the first patient was a man, 37 years of age, seen on October 27, 1917. He gave a history of having noticed a swelling over the sacrum seven months before which was discharging pus. Physical examination showed two openings in the skin in the midline and two or three supplementary openings at the side. A probe could not be passed through from one to another of these openings, but fluid injected into one opening appeared through the others. An operation was performed on November 12, under local anesthesia (0.5 per cent. novocaine).

The main tract was opened and drained. It was found to contain a ball of hair about the size of a hazelnut. The entire area involved was excised elliptically, and the wound packed. Healing was complete in about five weeks. The second case was very similar to the first. This patient was an Italian, 26 years of age, who gave a history that for the past two years abscesses formed over the sacrum and broke. Several openings started as pimples. Abscesses had been twice opened by his private physician and four months ago he had been operated on under general anesthesia at a hospital and stayed five days. He had a recurrence and, on November 19, 1917, under local anesthesia, an excision was done and the wound packed as in the previous case. From the standpoint of diagnosis these cases were interesting, because they were not recognized as a rule and that was the reason they were not cured. One of these patients had three openings on each side, and looking at them casually one would have said that he had a fistula or that it might be an infected sebaceous cyst, a dermoid, or a tuberculous condition. It was quite generally agreed that these pilonidal cysts were due to developmental defects. The ectoderm did not approximate in the usual way. Dr. Markoe had published a paper in the *American Journal of Medical Sciences*, in 1902, in which he showed that about 30 per cent. of infants at birth had this defect. It had the appearance of a dimple and usually was superficial and tended to become obliterated as the child developed, but in some persons who had this defect and became fat the superficial tissues closed over the depression, enclosing hairs in the sac in which an abscess finally developed. The important point was to recognize the condition and then to dissect it out thoroughly and not to sew up the wound, but to pack it. If it was sewed up it would not heal but if it was packed it would be absolutely cured.

Epithelioma of Anus.—Dr. FRANK C. YEOMANS presented this case. He stated that the patient was a man, 71 years of age, who gave a history of having had erysipelas in a wound of the left arm incurred in the Civil War. He drank liquor until two and one-half years ago. There was no history of syphilis. When first seen, on August 5, 1916, he stated that sixteen months before he had had protruding piles due to constipation. Five months before the sphincter had been stretched under gas anesthesia. Two weeks later he was operated on for hemorrhoids under local anesthesia. The wound never healed and continued to bleed after this operation. He was told, however, that he did not have cancer. His weight had dropped from 197 to 145 pounds during the six months before the speaker saw him. Physical examination showed his general condition good; the chest and abdomen negative. Rectal examination showed the outlet of the rectum relaxed and excoriated. There was a trough in the posterior commissure. This bled on contact and was indurated for one and one-half inches, or the length of the anal canal. The induration extended one-half way around the canal on each side and into the post-anal tissue, where there was a mass about the size of a hickory-nut. The feel was that of cartilage. Biopsy showed that the growth was malignant. The right inguinal glands were discreetly enlarged. The patient said they always were so. He was operated upon on August 7, 1916. A typical perineal excision of the rectum, including the sphincters and adjacent tissue, was done and five inches of the bowel was removed. The levator muscles were sutured to the gut and the mucosa to the skin. A tube was placed in the rectum and another in the sacral cavity. There was very little bleeding and not a vessel was tied. At the end of the operation the patient left the table in good condition, with a pulse of 92 and needed no stimulation. He left the hospital eighteen days later. His weight has gone up, from 145 to 161½ pounds, during the seventeen months since the operation, has no pain and feels well and strong. There was primary union of the gut to the skin and not the amount of scar tissue that one usually got. He had control of the bowel by regulating his diet, and the only discharge was some mucus. His bowels moved three or four times a day. He wore a pad because of the discharge of mucus. Following the operation he had a sacral lymphangitis. The pathologist's report stated that the growth was a squa-

mousselled epithelioma of the anus, which was very malignant. The speaker had consulted with several colleagues as to whether the patient should be treated with the x-ray or radium, but it was thought best not to subject him to such treatment at the present time.

Dr. DOUGLAS stated that he had seen quite a number of cases of pilonidal cyst at St. Luke's Hospital, perhaps five or six cases a year. He thought they were all developmental in origin, due to the infolding of the ectoderm and epithelium, and not the result of an accumulation of fatty tissue and the closing over of a depression.

Dr. YEOMANS said he agreed with Dr. Douglas that pilonidal cysts were absolutely due to a developmental defect. As he had stated, about thirty per cent. of infants had this tendency, but it was outgrown in most persons. Occasionally in a stout person it was not outgrown, and because of the accumulation of fatty tissue about the depression, and possibly because of a lack of cleanliness in some cases, the depression became deeper and was enclosed and finally an infected cyst developed. In one of the cases presented there was a ball of hair the size of a hickory-nut enclosed in stratified epithelium. The point to be emphasized was that this condition was not usually recognized by the physician or the surgeon, but after he had seen two or three he would recognize them readily and would make a thorough excision, going right down to the periosteum. Before beginning the operation it was advisable to inject methylene blue to be sure that one had reached all the fistulae, or there would be a recurrence.

Sarcoma of Tonsil; Radical Operation.—Dr. GEORGE H. SEMKEN presented this patient, a man 49 years of age, a clothier by occupation, who came under observation on June 19, 1917. His family history and previous personal history were negative. He had not been subject to tonsillitis, and there was no definite etiological factor except possibly his free use of cigars for many years. During the preceding six months, he had some difficulty in swallowing and occasional pain in his throat; about one week previously, he had noticed that the right tonsil was considerably enlarged. There were no other symptoms. Examination showed a walnut-sized, smooth, rounded mass at the site of the right tonsil, which had drawn down the faucial arch on that side, and had pushed the uvula to the left of the median line. The mass was of firm consistency, pink in color, and covered with mucous membrane except in two small areas—one near the uvula, which was gray but unbroken, and one near the anterior faucial pillar, which was dull red and seemed to be an erosion as from a tongue depressor or other instrument. The mass was well defined, and showed no invasion of the surrounding tissues. The other tonsil was small and seemed normal. There were no palpable lymphatic glands in the neck. The operation was done on June 22, 1917, at the New York Skin and Cancer Hospital, under ether-colonic anesthesia. As a first step, the radical extirpation of the submental, submaxillary, digastric, and carotid lymphatic gland packets was done, and the neck wound closed with sutures, provision for drainage being made. The tonsil tumor was then removed through the mouth. Three silk traction sutures were placed—one above the anterior faucial arch on the right side, one at the lower end of the right anterior faucial pillar, and one at the base of the tongue. The mucosa was then incised wide of the tonsil rim, and the tonsil was removed with its capsule. A piece of the uvula was included also. The bleeding was checked with Kocher hemostats and the Blunk forceps; and the entire wound was then cauterized with the Percy cautery at a dull red heat. As a final step, the tonsil cavity was packed with iodoform gauze, which was held in place by sutures passed through the anterior and posterior wound margins, and tied over the gauze. The patient's recovery from the operation was uneventful. There was a sharp febrile reaction for a few days, but the temperature soon became normal and remained so. The neck wound healed per primam. The tonsil packing was removed after 24 hours, and the wound in the fauces gradually closed. As cicatrization advanced, the uvula was drawn toward the right side, so that at present, with the healing process complete, the uvula lay against the right side of the fauces. A point to be emphasized in the use of the cautery in the mouth and

pharynx was the necessity of preventing the entrance of smoke into the bronchi and lungs, with each inspiration. This was best accomplished by the use of a small motor blower, attached to a pharyngeal tube, which blew the smoke out of the mouth as soon as it was formed.

Cicatrix Deformity of the Hand; Flap Transplantation and Corrective Apparatus.—Dr. SEMKEN presented this patient also, a man now 25 years of age, who was presented at a meeting of this section on March 2, 1917. At the age of nine months, he sustained a severe burn of the palm of the right hand by falling into a small open fire. As a result of the loss of tissue, cicatrization, and a secondary contraction of the palmar fascia, a marked flexion and adduction deformity developed. In addition, the fifth finger had become fused with the palm. On October 20, 1916, the scar tissue and contracted palmar fascia were excised and replaced with a flap of skin and subcutaneous fat from the left axilla. It was impossible at that time to obtain full extension in the hand and fingers, because the tendons, blood vessels, and nerves were all too short to allow it. It seemed probable, however, that this correction could be accomplished later by mechanical means; and that plan was followed as soon as the hand and fingers had healed. Full extension was obtained within a short time by having the patient place his right hand upon a table, palm down, and press upon the dorsum of the hand to flatten it down. As soon as this stage was reached, the corrective apparatus was used to overcome the adduction in the fingers. The apparatus consisted of a fixed palmar aluminum plate, extending from the metacarpal heads to the upper forearm, and held in place by a laced leather cuff attached to its arm part. At the metacarpal end, a hand-plate provided with wide metal loops for the fingers was attached with a swivel pin, which allowed free motion of the plate from side to side. The extent of this motion was controlled by a bar held by a swivel pin under the distal ulnar end, and passing through a fenestra in a fixed curved bar attached at the radial side of the large arm plate. The movable bar was round and had a screw thread on its radial half. By means of a screw head on the movable bar, on the outer side of the fenestra, the finger plate could be drawn radially as far as the patient's tolerance allowed. Fixation of the metacarpal heads was accomplished with a padded dorsal bar, hinged on short uprights attached to the fixed plate. The patient wore this apparatus over night and whenever possible during the day, when he was not at work; and he has been able to bring his fingers into their normal axis again. Although the fingers showed no tendency to resume the old, faulty position, he still wore his apparatus occasionally as a precautionary measure. As a last step in the "reconstruction" of this hand, the Agnew operation was done on the webs of his fingers on November 13, 1917. The dorsal triangular flap, utilized in the Agnew operation, tended to break the U of scar tissue, between the fingers (along the margins of the flaps on the fingers), and thus to prevent subsequent contraction, shortening of the U, and webbed fingers.

Dr. EDWARD PETERSEN asked Dr. Semken whether he ligated the external carotid.

Dr. SEMKEN replied that he did not ligate the carotid artery in these cases. After ligation of the common carotid, collateral circulation was established within a few minutes through the circle of Willis (as was shown, he believed, by Dr. Llewellys Barker in cases of pulsating exophthalmos). After ligation of the external carotid, collateral circulation was not established so soon, but it did occur relatively rapidly. Instead of the destructive permanent ligature, the method of choice seemed to be the placing of a strong silk or linen thread about the artery, without tying it. The ends of the ligature were allowed to emerge from the wound, which could then be wholly closed by suture. If hemorrhage occurred during the tumor operation, traction could be made upon these long ends, to angulate and compress the artery. As soon as the bleeding vessel in the throat had been caught, the traction upon the carotid ligature could be released. At the end of the operation, the ligature could be readily removed by gentle traction upon one of the thread ends. In most of these cases, the tumor operation and that upon the glands of the neck were done in one stage; and it was a simple mat-

ter to place the ligature during the neck operation. Where these operations were done separately, in two stages, a small incision could be made for placing the ligature.

Dr. CHARLES H. FARR asked Dr. Semken how he made the clinical diagnosis of epithelioma in this case; it had been his experience that many of the cases that he supposed were epithelioma of the tonsil proved to be syphilitic or inflammatory conditions.

Dr. SEMKEN replied that the mass had the appearance of a new growth rather than that of syphilis or other inflammatory process. The surface was practically intact; the consistency was uniformly firm, and there was no hyperemia or infiltration in the surrounding tissues. The Wassermann examination was negative. However, he had not relied wholly upon his own judgment, but had the confirmatory opinion of other colleagues who had examined the patient. Dr. Semken said he was glad to have this opportunity to express his opinion in reference to biopsy. While biopsy was, undoubtedly, occasionally necessary, especially in the diagnosis of cancerous processes in luetic patients, it should not be forgotten that incision into a cancerous mass could greatly increase the malignancy of the growth, and favor metastasis. When biopsies were necessary, the patients should be made to understand that the operation must be done at once, if the report of malignancy was returned. When one had seen instances in which a small early cancer, after five or six biopsies, became converted into large, actively growing tumors, one could not help feeling strongly on this point. It was regrettable, therefore, that many boards of health had urged these biopsies, without emphasizing their danger.

The Use of Small Bone Transplants in Bridging a Bone Defect.—Dr. FREDERIC W. BANCROFT read this paper, which he illustrated with lantern slides. He stated that in certain types of fractures of one of the bones of the forearm where there was malunion with loss of substance it was difficult to properly brace the resulting defect. The bone was too small to maintain a transplant in position by a Lane plate or other device. In performing bone transplants in dogs, while pursuing the study of bone repair, he was struck with the universally good result obtained by transplanting small bone fragments, one to two mm. in size, to fill the defect in the shaft of the radius. The method employed in the animal experiment was as follows: With the animal under ether anesthesia, the radius was exposed for the distance of about 4 cm.; the surrounding structures were dissected free from the shaft, and a portion of the shaft about 3 cm. in length was removed. The periosteum was excised for a distance of one to two cm. from both cut ends of the radius. The excised piece was freed from its periosteum, split lengthwise, and all visible endosteum removed. It was then cut into small fragments, one to two millimeters in size, and these little fragments were inserted in the bone defect. The muscle, fascia, and skin were closed in layers, and a gauze dressing followed by a plaster of paris bandage applied. At regular intervals following the operation radiographs had been taken and the dogs sacrificed. The leg was then examined clinically and later decalcified sections were studied microscopically. In studying radiographically a series of animals at intervals after the operation it was seen that the transplants became gradually smaller, while about them a formation of new bone occurred. At a later stage the form and contour of the shaft was reestablished. Microscopical sections, taken at periods varying from seven days to one and one-half years after the operation, showed that there were two main factors involved in the repair of these bone defects, namely: (a) the bone fragments; (b) the organization of connective tissue about the fragments. Dr. Bancroft described in detail the microscopical changes that took place and showed that as they progressed the bone fragments were gradually absorbed and lost their identity in the mass of new bone forming from connective tissue. In a year the medullary canal had been established and one found tubular bone that was difficult to distinguish from the normal shaft. The Haversian canals had reformed in the direction of the long axis of the shaft. The bone was covered with a connective tissue layer resembling periosteum. Too much importance had been

placed by most authors upon the origin of the bone cell as the vital factor in bone repair. This had clouded our conception of the process. Bone was mesoblastic in origin, and in its repair it was found that calcium salts were deposited on the intracellular elements of connective tissue forming new bone. The connective tissue cell then, by a process of metaplasia, became a bone cell. Periosteum was a connective tissue, and hence was prone to form bone, but it was not the only connective tissue that had this function. If this theory were assumed it would explain the extra skeleton formation of bone as in arteries, myositis ossificans, ovaries, kidneys, etc. From the clinical point of view this procedure offered an adequate method of bridging a bone defect if there was another bone present to act as a splint, and if it was possible to hold the bones in adequate position by external support. It offered the advantage of not having to expose a very large area, and of not having to introduce a foreign body.

Dr. WHIPPLE referred to the studies of Dr. St. John of cross-sections of bone after the reduction of fractures and stated that both Dr. St. John's observations and his own studies along this line were the same, so far as the transition from one kind of tissue to another was concerned, as those Dr. Bancroft had described. The same principle that Dr. Bancroft had just shown, the transplantation of small bone fragments, had been shown by Dr. Hibbs to be applicable to Pott's disease. Dr. Hibbs had done quite a number of operations for Pott's disease, using the bone fragments, and stated that he obtained better results with this method than by his own method or that of Dr. Albee.

Dr. CHARLES E. FARR stated that he had been impressed by the fact that comminuted fractures united more rapidly than simple fractures, and this was probably explained by the fact that there were a number of fragments that stimulated bone growth in the comminuted fractures. In operation for non-union, in which bone transplants were used, it was probably not so much the large transplant that caused the union as because of the small fragments of bone or bone dust left in the operative field that stimulated bone regeneration. The same was probably true of the operations in which Lane plates, etc., were used. Mackewen, some years ago, reported a case in a child in which regeneration of a whole humerus resulted from the implantation of a number of tiny bone fragments.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

HYGIENE AND MANAGEMENT OF PREGNANCY. By MORRIS J. KROHN, M.D. 32 pages. Price, 35 cents. Published by the Author, Denver, Colo.

LA GANGRENE GAZEUSE. By ANDRÉ CHALIER and JOSEPH CHALIER. 386 pages. Illustrated. Price, 8 fr. 80. Published by Librairie Felix Alcan, Paris.

LES FRACTURES DE GUERRE DU MAXILLAIRE INFÉRIEUR. Par Le D. A. HERPIN. 153 pages. Illustrated. Price, 4 fr. 40. Published by Librairie Felix Alcan, Paris.

ANNUAL REPORT OF THE MASSACHUSETTS COMMISSION ON MENTAL DISEASES FOR THE YEAR ENDING NOVEMBER 30, 1916. 344 pages. Published by Wright & Potter Printing Co., State Printers, 32 Derne Street, Boston.

MANUAL OF SPLINTS AND APPLIANCES FOR THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY, 1917. 208 pages. Illustrated. Price, 75 cents. Published by Oxford University Press, New York.

REPORT OF THE PHILIPPINE HEALTH SERVICE for the fiscal year from January 1 to December 31, 1916. By J. D. LONG, M.D., Director of Health. 251 pages. Published by Bureau of Printing, Manila.

A PRACTICAL TEXT-BOOK OF INFECTION, IMMUNITY AND SPECIFIC THERAPY. By JOHN A. KOLMER, M.D., D.P.H., M.Sc. 978 pages. Illustrated. Price, cloth, \$7.00 net; half morocco, \$8.50. Published by W. B. Saunders Company, Philadelphia and London.

THEORETICAL CONSIDERATIONS OF MENTAL DEFICIENCY.

BY M. G. SCHLAPP, M.D.,

NEW YORK.

PROFESSOR OF NEUROPATHOLOGY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

BECAUSE of the unusually large amount of clinical material which has come under the writer's observation in the past few years, he has had a rather exceptional opportunity for extensive study on the subject of this paper; and he hopes to be able to justify his desire to present to the medical profession a series of articles on mental deficiency.

In the last four years over ten thousand cases have been closely studied in the writer's clinic, "The Clearing House for Mental Defectives," at the New York Post-Graduate Medical School and Hospital. These cases coming from the various courts and other tribunals of the City of New York, as well as from many charitable institutions and other agencies, represent a group of individuals unable to adjust themselves properly to their environment, either because of a true amentia or as the result of some affective disturbance of their mentality.

These cases involve a sociological as well as a medical problem and it therefore seems wise to consider them from these two viewpoints.

The term "mental deficiency" has hitherto been rather indefinitely applied. By some authors it has been made to include both insanity and feeble-mindedness. By others, it has been used specifically to characterize feeble-mindedness alone. The writer, however, feels that a broader meaning than the latter ought to be attached to this term, that not only the aments be included in this group but also those individuals who are not able to adjust themselves to their environment, because of a mental instability or of some affective disturbance, conditions which cannot be classed as psychoses.

"Mental deficiency" has up to a recent period taken a more or less "back seat" in the forward march of medical and psychological research; it has been a stepchild to psychiatry, and its tutelage an apparently hopeless problem. However, during the last decade or two more interest has been shown in the medical as well as the sociological aspect of this problem.

Records show that in early ages different manifestations of insanity and epilepsy were described, the latter by Hippocrates, while Aretaios described different types of the former. It was not, however,

until much later that idiocy attracted any attention.

Avicenna (980-1037 A. D.) spoke of different types of feeble-mindedness. In the Middle Ages the belief that those showing symptoms of feeble-mindedness were possessed of the devil is strikingly shown by remarks of Luther made to the ruler of the principality of Anhalt to whom he recommended that a twelve-year-old feeble-minded child should be thrown into the water and prayer be delivered to God that He should take the devil from his child, as such children are (*massa carnis*) without soul.

Paracelsus (1493-1541 A. D.) devoted much time to cretins and it seems that from that time on this condition has been quite frequently described; in fact, the first institutions for the feeble-minded were built for the care of cretins in Chur, Gräbünden, and in Admont Steiermark.

A number of feeble-minded and epileptic persons were treated in the Bicêtre Hospital in Paris. In some of the other hospitals and cloisters small divisions were established for the feeble-minded.

In the eighteenth century idiocy was considered a form of insanity, no differentiation being made at that time between amentia and dementia.

In 1802 Joseph and Carl Wenzel (*über den Kretinismus, Studien in Salzburg, Wien*) described a number of characteristic symptoms of cretinism, but even here no sharp differentiation was made between dementia, which developed in the life of an adult person, and amentia, which was due to the lack of mental development.

About this time, 1801, the first step was made in the attempt to train the feeble-minded. This was done by a French physician named Etard who is said to have had some results in training the "wild man of Aveyron."

This method of training was further developed by his pupil, Seguin, whose work at the Bicêtre Hospital laid the foundation for the system of training the feeble-minded, which has been taken up by practically all private and state institutions established for the care of the feeble-minded of the present time.

In 1846 Seguin published a work entitled, "*Traitement moral, Hygiène et Education des Idiots et des autres Enfants Arriérés.*"

At about this time, and no doubt to a certain extent influenced by the teachings of Seguin, private individuals and States created schools and institutions for the care of the feeble-minded in which the principal method of treatment was the training of these individuals.

In recent years the idea of seeking the causes of mental deficiency seems to have been and is uppermost in the minds of a number of medical

investigators in different countries. Tredgold, recognizing the importance of this fact, classified the feeble-minded into two large groups, namely, feeble-mindedness caused by intrinsic factors and that caused by extrinsic factors.

Intrinsic factors, Tredgold says, are hereditary influences which modify germinal plasm before conception takes place, and the form of amentia it could produce may be termed primary.

Extrinsic factors are those conditions of the environment which affect the development of the brain (and body) during either antenatal or postnatal life and in this case the amentia may be termed secondary.

The following is Tredgold's classification:

A. Intrinsic—Hereditv.

1. Disease of nervous system.
2. Alcoholism.
3. Tuberculosis.
4. Syphilis.
5. Consanguinity.
6. Age of parents.

B. Extrinsic—Environment.

1. Before birth.
 - (a) Abnormal conditions of the mother during pregnancy; (1) Mental; (2) Physical.
 - (b) Injuries to the fetus.
2. During birth.
 - (a) Abnormalities of labor.
 - (b) Primogeniture.
 - (c) Premature birth.
3. After birth.
 - (a) Traumatic.
 - (b) Toxic.
 - (c) Epileptic and infantile convulsions.
 - (d) Malnutrition.

Weygandt speaks of the difficulty of the classification of the feeble-minded but attempts to bring out types of feeble-minded individuals under the following classifications:

Historical Groups:	Groups
Feeble-mindedness due to deficiency in training.....	1
Feeble-mindedness due to sensory deficiency.....	2
Endogenous Feeble-mindedness:	
Microcephalus, brain malformations.....	3
Feeble-mindedness due to inflammatory processes:	
Inflammation of the brain (encephalitis microcephalus, microgyrus, atrophic sclerosis and gliosis, porencephalus).....	4
Encephalitis.....	5
Hydrocephalus.....	6
Endogenous Groups:	
Amaurotic family idiocy and related groups.....	7
Tuberous hypertrophic sclerosis.....	8
Mongoloid degeneration.....	9
Infantilism:	
Dystrophic infantilism due to the milieu, malnutrition, intestinal disturbances, vitium cordis (pulmonary and mitral infantilism, alcohol and other poisons, infectious disease, lues, tuberculosis, malaria, pellagra).....	10
Glandular Infantilism: status Thymicolymphaticus and Idiotia thymica.....	11
Dysthyroidism: hyperthyroidism (Basedow), Myxedema and thyroprivia degeneration.....	12
Endemic cretinism, atromous amentia.....	13
Dysgenitalism.....	14
Dyspituitarism: Acromegaly with amentia, adiposogenitalis with idiocy; hypopituitary infantilism, dyspnealism.....	15
Dysadrenalism.....	16
Pluriadular infantilism.....	17
Syphilogenous idiocy, imbecility, debility; syphilogenous infantilism and infantile paralysis.....	18
Alcoholic developmental disturbances.....	19
Athetotic feeble-mindedness.....	20
Chorea, with a disturbance of mental development.....	21
Spasmodophilia and epilepsy with feeble-mindedness.....	22
Rachitis with feeble-mindedness.....	23
Chondrodystrophy with feeble-mindedness.....	24
Turmschadel with feeble-mindedness.....	25
Early types of Psychoses and Psychoneuroses:	
Dementia praecox with disturbance of mental development.....	26
Dementia infantilis (praecocissima).....	27
Manic-depressive insanity in childhood.....	28
Hystero-degenerative insanity in childhood.....	29
Neurasthenia in childhood.....	30

In England in 1904 the Royal Commission on the Care and Control of the Feeble-minded was appointed, consisting of the Earl of Radner, chairman, W. P. Byrne, Chadwick-Healey, C. E. H. Hobhouse, M.D., F. Needham, M.D., H. B. Donkin, M.D., C. Dunlap, M.D., H. D. Green, Rev. H. N. Burden, W. H. Dickinson, M.P., C. S. Loch, Mrs. Hum. Pinsent. The Royal Commission recommended the clinical classification of the mentally defective into four types:

1. A feeble-minded person is one who is capable of earning a living under favorable circumstances, but is incapable, from mental defect existing from birth or from an early age, (a) of competing on equal terms with his normal fellows; (b) or of managing himself or his affairs with ordinary prudence.

2. The imbecile is one who, by reason of mental defect existing from birth or from an early age, is incapable of earning his own living, but is capable of guarding himself against common physical dangers.

3. An idiot is one so deeply defective in mind from birth or from an early age that he is unable to guard himself against common physical dangers.

4. The moral imbecile is a person who by reason of an innate defect displays at an early age vicious or criminal propensities which are of an incorrigible or unusual nature, and are generally associated with some slight limitation of intellect.

La Page states (Feeble-mindedness in Children of School Age): "In all definitions of these conditions the lifelong and incurable character of the mental affliction should be emphasized, in order to distinguish it from (1) temporary mental affections, and (2) from backwardness or retarded mental development, which is due to adverse factors in infancy and childhood. Temporary insanity may be cured and a backward child may be brought up to the normal level by suitable treatment, but a mentally deficient child, though amenable to treatment and training to some extent, can never be rendered normal."

Further quotation from La Page from the report of the Royal Commission under Causation: "When dealing with the causation of mental defect the Commissioners found that twenty-five out of thirty-five witnesses attached supreme importance to the fact that, in a very large proportion of the cases of mental defect, there is a history of mental defect in the parents or near ancestors. The twenty-five witnesses who held this opinion had all had a very large experience and had devoted special attention to the subject. Sir Clifford Allbut said: 'I regard feeble-mindedness (if not accidental) as always hereditary, or, in other words, it is a ratio of variation. I have never met with a case of manufactured feeble-mindedness apart from some accident at birth or afterwards. . . . I attach great weight to inheritance. . . . Feeble-minded persons are prolific; the thing can only be bred out.'

"Dr. Ashby, Medical Officer to the Special Schools at Manchester, said: 'In at least 75 per cent. of the children with amentia that I have examined there was a strong probability that the amentia was hereditary and primary (i.e. spontaneous, not due to external influences).' He further says that he has observed no special tendency in the children of alcoholics or of women who suffer privation during pregnancy or in those children who live in unfavorable conditions subsequent to birth, to develop amentia. The term 'amentia' is here used to cover all grades of mental defect in early life.

"Sir E. Ray Lankester holds: 'That congenital feeble-mindedness is spontaneous originally and truly hereditary subsequently, and is not brought about by starvation and other such conditions; it is more probably due to easy conditions of life and the absence of the selection that obtains amongst more primitive men.'

"On the other hand, it is only fair to quote Dr. Mer-

cier's evidence, which was: 'That not only is the frequent transmission of feeble-mindedness by inheritance not proved, but, also, that the organic defect of brain which underlies feeble-mindedness may be often the result of external influences which during childhood affect the growth of the brain injuriously.'

"In conclusion, the Commissioners sum up:

"1. That both on the grounds of fact and of theory there is the highest degree of probability that 'feeble-mindedness' is usually spontaneous in origin—that is, not due to influence acting on the parent—and tends strongly to be inherited.

"2. That, especially in view of the evidence concerning fertility, the prevention of mentally defective persons from becoming parents would tend largely to diminish the number of such persons in the population.

"3. That the evidence for the conclusions strongly supports measures which, on other grounds are of pressing importance for placing mentally defective persons, men and women, who are living at large and uncontrolled, in institutions where they will be employed and detained; and in this and in other ways kept under effectual supervision so long as may be necessary."

As is true of all new problems, one hears statements made concerning feeble-mindedness that are neither conducive to a better understanding, nor have they any basis in fact. These statements are usually made by persons without adequate training, who are, nevertheless, considered as experts by the laity. For example, it has been asserted that feeble-mindedness is a reversion to the primitive type of man; that the feeble-minded are physically normal and so on. Such doctrine is incorrect; furthermore it does harm by confusing the subject and discouraging really serious and scientific investigation.

Mental deficiency is the result of a disturbance of the functional activity of the brain, due either to a gross anatomical lesion of the brain, or special sense organs, with connections; or, due to a serious disturbance of the metabolism of the brain cells. In amentia this condition develops before or shortly after birth. In affective disturbances with or without definite intellectual deficiency the metabolic disturbances may develop later, as in the adolescent period of the individual's life or even later.

For a working basis, I should like to suggest dividing mental deficiency into three groups:

1. In the first group I would place all cases in which the growth of the brain has been impaired, the physiological activity of cell production having been disturbed, resulting in abnormal cell division. This we may call the **Formative Type**.

2. The second group embraces the cases in which the brain cells are not lacking in number, but in these the proportion of the chemical activating substances, which are necessary in order that the cells react normally to stimulation, is disturbed. There may be an excessive amount or a deficiency of one or more hormones in the blood, or, on the other hand, there may be present in the blood a foreign toxin generally or selectively disturbing the metabolism of the brain cells. This group may be called the **Functional Type**.

3. The third, or **Traumatic Type**, includes those cases in which the mental deficiency is due to a definite physical injury of the brain. Up to the time of the trauma the brain may have been anatomically and physiologically unimpaired, but afterward, on account of inflammatory reactions, lacerations, hemorrhage, tumors, or other such conditions, destruction of brain tissue results.

Before considering the above types in detail, however, it seems advisable to outline briefly the theory upon which this classification is based.

Living cells present three distinct life processes: (a) nutritive activity, (b) formative activity, (c) functional activity.

The nutritive activity is that process whereby a cell is capable of taking into its body from the surrounding medium substances which it may store there as potential energy.

The formative activity is that process whereby a cell is capable of dividing and forming one or more daughter cells.

The functional activity is that process whereby a cell, responding to a stimulus from without, performs some act; the contraction of a muscle cell, secretion of a gland cell, reaction of a nerve cell, etc.

These three activities are intimately related to one another. Both the formative and functional processes when active draw upon the same store of energy, laid in by the nutritive process; hence, they are rival consumers and one becomes active at the expense of the other's activity.

The formative process is very active during the formative period of an individual's life, and as the different cells become more active functionally the formative process becomes less active and finally ceases or remains quiescent. Thus we see that highly specialized functional cells have lost the formative activity entirely; nerve cells, muscle cells, etc.

Only the low type cells, such as epithelial, endothelial, connective tissue, and other similar cells retain, to a greater degree, their formative process, and hence, in these cells, it may be more easily awakened to activity (tumor formation).

In order that these three processes may act in a normal way the medium which surrounds the cell and from which the nutritive activity draws its supply must be normal—contain all the chemical materials in proper solution and proper proportion. Should any of the chemical substances be missing or their normal proportions in the medium be disturbed, then any or all of the life processes may become disturbed. Instance the lack of thyroid substance or the excessive amount of this substance in the adult with a resulting disturbance of the functional activity of the body cells. Should there be present in the medium a foreign substance whose effect on the cells is toxic, then any one or all of the life processes may become disturbed, *e. g.* the action of strychnine, morphine, alcohol, and other toxic substances.

The living body is composed of many different groups of cells which have different physiological values. We have evidence enough at hand to know that the life processes in these different cell groups are selectively affected by different chemical substances normally found in the medium, namely, the hormones; so a disturbance in the chemical balance in the medium would selectively disturb certain groups of cells, as also would the presence of toxins selectively affect certain groups of cells.

If in the fetus or in the early growth period of an individual the chemical balance of the medium be disturbed, either due to increase or decrease of the normal amount of chemical substances (hor-

mones), or due to the presence of a foreign toxic substance, then the formative activity may be the one to suffer most, in consequence of which we shall have some organ or part of the body imperfectly developed according to the degree and selectivity of the disturbance.

Later in the life of an individual as the formative activity is subsiding and the functional activity is increasing, it will be the latter which will suffer as a result of a disturbance of the chemical balance of the medium.

In considering the life processes of the cells in the human organism it should be borne in mind that formative activity does not suddenly cease and functional activity suddenly begin, but that there is a gradual diminution of the one and an equally gradual onset of the other activity.

The effect of disturbed hormonal balance on nutritive activity cannot be so directly measured. It can find expression only indirectly through its two dependents, the formative and functional activities. During intrauterine life formative activity is in the ascendancy; it thereafter progressively declines while functional activity as steadily increases. It is not until some time after adolescence that formative activity becomes entirely quiescent in most organs of the body.

This point can be strikingly illustrated by two widely different clinical types, caused by the same hormonal disturbance, namely, cretinism and myxedema in the adult. The etiological factor in each is the same (deficiency of thyroid), yet the clinical manifestations are widely different and for the following reasons:

In the one (cretinism) the hormonal disturbance occurs at a period of development when both the formative and the functional activities are equally potent, and in a well-marked case of cretinism the distorted formative activity is manifested by well-marked organic lesions, such as deficiency in the number of brain and other cells of the body (manifested by dwarfing, imperfect osteogenesis, anatomical defects in the brain with resulting mental abnormality, etc.), and the disturbance of functional activity by varying degrees of mental torpor. In the other type (myxedema) the hormonal disturbance occurs at a later period in life, when formative activity is quiescent and the anatomical development of the brain is normally and fully completed, hence it is unaffected by thyroid insufficiency; therefore in this type it is the functional activity alone which is disturbed. In the one type (cretinism) if disturbance of formative activity has been prolonged for a sufficient length of time so as to inhibit the production of a sufficient number of brain cells for normal activity, no amount of thyroid therapy will suffice to restore the functional activity to normal, while in the other type (myxedema), in which no disturbance of the formative activity has occurred, complete restoration of functional activity rapidly follows the administration of thyroid extract.

In the beginning of a given hormonal disturbance the clinical manifestations may be those of a pure type (*i.e.* myxedema), but after a variable length of time other endocrine organs may become secondarily involved, so that the clinical type may be mixed.

Permit me at this point to bring home in a striking way to the reader the fact that if we hope to benefit or cure the cretin we must get that individual at the earliest possible moment before definite anatomical deficiencies have occurred, and supply that organism with the normal amount of thyroid substance through the whole period of formative activity, so that these anatomical defects cannot arise. If this can be done, we may hope to keep the functional activity in a normal state. The advice that thyroid substance should not be given over a long period of time in such a case is a mistake, because the normal body requires it, and if the gland cannot furnish the normal amount it must be given artificially.

There is a very close analogy between the disturbance of formative and functional activity produced by deficiency of thyroid hormones and similar disturbances produced by defects in the other endocrine organs of the body—the pituitary, adrenals, parathyroids, pineal gland, Leydig cells of the sex glands, etc.—and as in the case of thyroid insufficiency, these disturbances vary with the period of life at which the hormonal deficiency occurs.

While disturbances of the formative and functional activities are manifested by definite clinical phenomena, disturbances of nutritive activity, on the other hand, are quite impossible of demonstration as such, because they will manifest themselves either through a disturbance of the formative activity, or by a disturbance of the functional activity, depending upon which one of these two processes is active at the time; therefore, it seems advisable to ignore, for the present, the nutritive process in this classification.

A functionally active cell has what we might theoretically term a threshold of functional activity, namely, the point at which a given stimulus just begins to cause a functional reaction in the cell. Should the stimulus fall below this value, the cell would not respond. The reaction of the cell will increase with the increase of the strength of the stimulus above the threshold.

The threshold of functional activity is more or less constant in animals under normal conditions, but it may be raised or lowered by a change from the normal in the proportion of the chemical substances (a disturbance of the proportion of the hormones) in the medium in which the cell lives, or it may be raised or lowered by the introduction into the medium of some foreign toxin.

As an example of the first condition, hyperthyroidism would illustrate the lowering of the threshold of functional activity of many of the nerve cells as well as other body cells, causing a marked instability of the protoplasm of the cell body. Hypothyroidism, on the other hand, would serve to illustrate raising of the threshold of functional activity of the cells in the central nervous system as well as in other body cells, because of the resulting marked stability of the protoplasm, making it impossible for the afferent impulses to elicit response and be translated into functional activity.

As an illustration of the raising of the threshold of functional activity by toxins may be mentioned the effect of ether, which acts selectively upon certain centers of the nervous system, causing a state of unconsciousness, but not raising the threshold

of functional activity of certain lower centers in the central nervous system, circulatory and respiratory centers, etc., thereby allowing the patient to continue the function of these lower centers.

As an illustration of lowering the threshold of functional activity by toxins may be mentioned the effect of strychnine, which acts selectively upon certain groups of motor cells, producing marked instability of their protoplasm, resulting in abnormal excitation by afferent impulses.

The threshold of functional activity of those cells selectively affected by the above changes will either be raised or lowered, as the case may be. This selective action on the cells by hormones or foreign chemical substances is of the greatest importance, and the writer believes that by this only can we explain the great variety of clinical syndromes in the cases to be subsequently considered.

The cerebrospinal and sympathetic nervous systems are made up of a large number of complexly arranged neuron systems, which have been, step by step, evolved through a long period of phylogenetic development. Each system of neurones has a definite physiological value and must necessarily respond selectively to different chemical substances. If nature had not so arranged, such a complex organism as the human being could never have developed. Note the selective action of the product of the chromaffin system, interrenal system, thyroid, parathyroid, pituitary glands, etc., and the selective action of pilocarpine on the part of the sympathetic (sweat gland) and on part only of the autonomous nervous system (salivary glands).

Anesthesia would not be possible if it were not for the selective effect on the nervous system of ether, chloroform, etc. These substances temporarily raise the threshold of functional activity of the perceptive and apperceptive cells of the brain to such an extent that no impulses can reach them. They remain dormant, the person is unconscious, but the neurones controlling respiration, circulation, etc., are not so affected and hence life continues.

Thus we see that one of the fundamental principles in physiology is the selective affinity certain groups of cells have for certain chemical substances, and thus may affect the cells in such a way as to stimulate or inhibit one or all of the three life processes.

The functions of the higher nervous centers may, for all practical purposes, be divided into two groups, viz. (1) *intellectual* and (2) *affective*. The functions of these two departments of the mind are executed by a great number of systems of neurones in each department. It can therefore be inferred that intellectual activity and emotional activity are both exceedingly complex processes. From a close observation of cases, it appears that either the intellectual or the affective side may be disturbed independently of the other, and the disturbance may be expressed by over-activity or under-activity, or both the intellectual and the affective sides may be synchronously disturbed in the same individual. In other words, when the intellectual side is seriously affected so that its functions are not normally executed, we may have an intellectual deficiency without affective disturbance; while, on the other hand, an *affective* (psychopathic) disturbance may be

present without intellectual deficiency. Both these groups are, however, classified as mental deficiency.

The intellectual centers may be disturbed in three ways, viz., (1) The brain may not be normally developed and those neurones which are concerned with the intellectual processes may be deficient in number (formative disturbance). (2) The intellectual centers may be unable to functionate normally because some of the cells have been destroyed by trauma (traumatic type). (3) The neurones may be present in sufficient quantity and anatomically normally arranged and yet be incapable of functioning in a normal manner because the threshold of functional activity has been raised so high that the neurones cannot respond to stimulation (functional type, of which an example is myxedema).

The affective side of the mind may be disturbed in the same manner, viz., (1) Those centers which are concerned with the affective mentality may not be normally developed (formative disturbance). (2) Those neurones which functionate for the affective side of the mind may have been injured or destroyed (traumatic type). (3) The neurones may be functioning excessively or deficiently because of lowering or raising of the threshold of functional activity of the various neurone systems of this group (functional type).

Many individuals suffer with emotional instability (a disturbance of the affective side of the mind) because the threshold of functional activity of many of the neurones of this group has been lowered to such an extent that it is on the "hair-trigger." The emotional make-up of such individuals is temporarily (or permanently) in a state of chaos; under the influence of appropriate stimuli, which are insignificant to the normal person, they will cry out, fly into a fit of temper, commit unprovoked assault, and, although intellectually conscious of the folly of their acts, are totally unable to control these psychic discharges.

On the other hand, many persons are almost entirely devoid of emotion; they display no love, pity, grief, or joy. The thresholds of these specific neurone systems are so high in these individuals that they cannot be emotionally aroused—the whole mentality is occupied by the ego.

In this group of cases with affective disturbances are found most of the criminal types—individuals whose mental make-up is disturbed in one of its many aspects, *e.g.* the sex pervert, the kleptomaniac (in many instances), the person who, in an uncontrollable fit of temper, commits some act of violence toward another, and many other instances which limited space will not allow the writer to enumerate.

These two departments of the mind present no sharp line of demarcation. There may be an equal disturbance of the intellectual and affective departments, or the intellectual disturbance may be greater than that of the affective, or vice versa, while in still other cases one department may be normal and the other absolutely defective.

Our knowledge concerning stimulation and inhibition of the three life processes in the animal and vegetable kingdoms is still very limited. All efforts directed at the solution of the problem of mental deficiency must ultimately converge upon these questions:

What are the factors which stimulate the formative process to activity during a certain period of an individual's life (from the conception of the ovum to the period of maturity)?

What are the factors which may inhibit this process during the growth period (pathologically) and do inhibit this process after that period normally? Why does the physical growth of an individual cease, after maturity, in nearly every other department of his economy and yet persist with unremitting vigor throughout life in the hematogenous organs; what determines this selectivity?

What are the factors which keep the "threshold of functional activity" of a living cell at a constant norm so that this cell will respond normally to external stimulation? And, on the other hand, what are the factors which may raise or lower the threshold of functional activity of cells?

The present state of our knowledge is insufficient for a definite solution of these intricate problems. However, from careful observation of clinical types of mental deficiency, and by rational interpretation and deduction from a small but clearly defined group of scientific data concerning the endocrine organs we can make certain observations with some degree of assurance.

This paper is presented to the profession in an endeavor to establish certain fundamental principles and to outline in a general way a rational conception of mental deficiency as it appears to the writer. No attempt has been made to discuss any specific groups of cases, but the writer hopes to present, in the near future, a series of articles in which he will make an effort to classify properly individual types of mental deficiency.

40 EAST FORTY-FIRST STREET.

COTTON-PROCESS ETHER.*

By W. G. HUDSON, M.D.,

NEW YORK AND WILMINGTON, DEL.

MEDICAL DIRECTOR, E. I. DU PONT DE NEMOURS & CO.; CHAIRMAN, SUBCOMMITTEE INDUSTRIAL DISEASES AND POISONS OF THE ADVISORY BOARD, COUNCIL OF NATIONAL DEFENSE.

PERHAPS the proper place to present a paper of this kind would be before the Society of Anesthetists, but there are a number of reasons why I prefer to present it before you. In the first place, I am not an anesthetist in the specialist sense, but only in the sense that we are all anesthetists at times, when the occasion demands. In the second place, and what is of more importance, this whole matter is so revolutionary, and so at variance with our old ideas in connection with ether anesthesia, that it would be accepted by the professional anesthetists only after prolonged argument and demonstration; and if there is as much to it as I believe, you will readily appreciate the necessity of getting the new ether produced at once in quantity and into the hands of our own and our allies' military surgeons.

I will first lay the proposition before you just as it is, and then take up in detail its development, and finally give a demonstration.

Please remember that it is not my idea, but that of a highly esteemed Canadian colleague, Dr. James Cotton, who is one of the surgeons at McGill Uni-

versity, Montreal. He has spent about five years in the study of ether from both the chemical and physiological standpoints, and to put his startling discoveries into a few words, they are as follows: He found that perfectly pure ether, for the manufacture of which an entirely new process had to be devised, is not an anesthetic at all, but produces, upon inhalation, merely a transitory stimulation similar to that from alcohol. Commercial anesthesia ether is by no means pure, but contains two sets of impurities, one of which produces the anesthesia, which we have been attributing to the ether itself, and the other the undesirable after effects which have been so great a drawback to the administration of ether. He then proceeded to charge his chemically pure ether with only the desirable impurities, going beyond the proportions in which they exist in ordinary anesthesia ether. When this was done, not only were the undesirable after effects eliminated, but it was found possible to produce an entirely new type of anesthesia, in which the patient can be maintained in a condition in which all sensation is abolished, but in which he is perfectly conscious, can carry on a conversation intelligently, and can even walk about, although rather unsteadily. If the amount administered is reduced, sensation begins to return, while, if it is pushed, the condition passes over into the ordinary surgical anesthesia, with loss of consciousness but without any intervening stage of excitement.

These ideas, when I heard of them, seemed so revolutionary that I paid scant attention to them, and when notified that Dr. Cotton was to give a demonstration upon the subject in Montreal last spring I did not feel like taking the time necessary to attend, but detailed one of my assistants to attend his lecture and demonstration, make notes, and send me a report. The following is his report:

June 20, 1917.

DR. W. G. HUDSON, MEDICAL DIRECTOR, WILMINGTON, DELAWARE.

DEAR DOCTOR.—Following instructions, I went to Montreal and attended the lecture given by Dr. James Cotton at McGill University on Wednesday, June 13, and the demonstration which he gave at the Royal Victoria Hospital on Thursday, June 14, 1917, on "New Ether."

In 1912, when acting as anesthetist at the Toronto General Hospital, Dr. Cotton noticed that the ethers manufactured by various concerns acted in varying ways. The ethers varied in amounts necessary to produce the required anesthesia, and the nausea and ill effects following the administration also varied. Dr. Cotton began his work to determine why this was so and why ether produced anesthesia. After five years of chemical analysis and experimental work he came to the following conclusions:

Pure ethyl ether will not produce either anesthesia or analgesia; ether owes its anesthetic powers to the impurities which it contains. The impurities he divides into three classes, as follows:

1. Irritative impurities which are: Aldehydes, ketones, methyl ether, propyl ether, butyl ether, amyl ether. Aldehydes present in the proportion of one-tenth of 1 per cent. will cause irritation. The bad smells of ether are due to organic acids.

2. Anesthetic impurities which are: Carbon dioxide and ethylene.

3. Toxic impurities like CO and peroxides.

Pure ethyl ether with the addition of ethylene or carbon dioxide will give complete analgesia without the loss of consciousness or without any unpleasant after-effects. Dr. Cotton claims that the sickness following the administration is due to alcohols and carbon monoxide. There is a possibility of carbon monoxide being formed in the ether when the top of the can is soldered

*Paper read before the Medical Conference Board of the National Affiliated Safety Organizations, Feb. 23, 1918.

in place. Superheated ether causes profound sickness after its administration.

Endorsement by the Canadian Medical Society.—The following is a paper issued by the Canadian Medical Society and based on Dr. Cotton's lecture on "New Ether." The reading of the paper on anesthesia yesterday showed:

1. That ethyl ether (pure) on administration produces only circulatory stimulation and peripheral vasodilatation (sleep following only if there is sufficient brain anemia resulting); *no less of pain sense.*

2. In commercial ether there also occur alcohol, and dimethyl ether, methyl ethyl ether, methyl propyl ether, which act the same as ether.

3. Outside of the physiological properties connected with the substances mentioned in Groups 1 and 2, these groups act only as a solvent for ethylene.

4. *Ethylene is the gas present in commercial ether which is responsible for analgesia.* It causes peripheral vasomotor spasm and circulatory depression.

5. Carbon dioxide may be used in place of ethylene, but the action is not so powerful and sleep intervenes usually before complete analgesia is obtained.

DEMONSTRATION GIVEN AT ROYAL VICTORIA HOSPITAL ON FRIDAY, JUNE 14, AT 8.30 A.M.

1. Administration of pure ether and ethylene to a cat. The animal became fully anesthetized in about three minutes. It was suspended by one ear and by its tail and showed no evidence of pain or discomfort, but still was able to see and walk around.

2. Patient was a Chinaman suffering with a severe infection of the right arm. Pure ether and CO₂ under pressure were given. At this time Dr. Cotton remarked the commercial CO₂ could not be used, but must be especially prepared and absolutely pure. The patient was anesthetized in about three and one-half minutes, and Dr. Edward Archibald made five incisions extending from the shoulder nearly to the elbow. During this procedure the patient was wide awake and looking about the room, but suffered no pain. After the anesthetic was stopped about thirty seconds the patient complained of pain and was thoroughly awake while the dressing was being done. He showed no signs of nausea or ill feeling.

3. The same cat that was used in No. 1 was brought in and pure ether was given. After several minutes of administration the exciting stage came on and the cat acted as if drunk. Later it quieted down somewhat, the effect of the slightest irritation showing that this ether did not act as an analgesic. Upon release the animal was able to stagger away.

4. Compound comminuted fracture of right elbow. Patient was given pure ether plus ethylene to the extent of about 2 per cent by volume. Patient went under after about two minutes and Dr. C. B. Keenan went in at the elbow and removed several small splinters of bone. During the operation the patient was wide awake and spoke fluently when spoken to and said he felt no pain; almost immediately upon withdrawal of the ether he complained of pain, but no nausea.

None of the subjects demonstrated showed any nausea either before, during, or after the administration of the ether.

In demonstration (3) there was an excitement stage, but none in 1, 2, or 4.

Following the demonstration by Dr. Cotton I had a good opportunity to talk to many of the Canadian physicians. They were all very strongly impressed by the demonstration and expressed their belief that ether made up to Dr. Cotton's standards would revolutionize the whole field of anesthesia and be a wonderful step in advance. They were all unanimous in the belief that Dr. Cotton's ether was far superior to ordinary ether as used at the present time, and seemed very proud of the fact that a Canadian physician should be the one to make such a wonderful discovery.

G. H. GEHRMAN, M.D.,
Resident Physician, Parlin Plant.

Since Dr. Gehrman made his report Dr. Cotton has written the matter up in greater detail and published it in the *Journal of the Canadian Medical Association* for September, 1917, to which any who are further interested may refer.

It is hard for many of us to accept such radical ideas as these without further confirmation, and it is quite evident that confirmation would be still harder for the rank and file of the profession to obtain, for one must have a well-equipped laboratory and unusual chemical training to go into the chemistry of ether as Dr. Cotton has done. I happen, however, to be more fortunately situated in this respect than most of us, through my connection with the DuPont Company. As you doubtless know, enormous quantities of ether are manufactured nowadays for use as a solvent in making smokeless powder. Therefore, it was clearly possible, with the help of one of our ether chemists (Dr. Foote) to check up Dr. Cotton's ideas, and this has been done. I have here some of the ethylene-charged ether, which I will shortly proceed to demonstrate.* About 58 operations have been done under this peculiar type of anesthesia without loss of consciousness, which Dr. Cotton has described, but I desire to increase the number greatly before advocating the setting up of manufacturing equipment for making this ether on a large scale. All of that so far made has been turned out in laboratory apparatus by a skilled chemist, and of course the cost by this method is prohibitive and the output small. Enough can be produced, however, to supply all of you gentlemen with samples if you desire to try it, and will promise to let me have your reports promptly.

You can readily see what a tremendous application this kind of ether would have in warfare, a field entirely apart from the ordinary surgical anesthesia. Even minor painful procedures, like a painful change of dressings, where anesthesia would not ordinarily be thought of, would call for it, with an enormous saving of suffering. As to its applicability in the minor surgery of the industries to which so many of us give our time and attention, I do not have to say anything, as you will all see the point at once. Another field in which striking results have been obtained is in obstetrics, where the small quantity needed to cause analgesia seems to have no influence in retarding the labor or in producing any other undesirable effects. In fact, its numerous applications continue to expand as one gives thought to the matter.

The analgesic condition seems to be very similar to the "primary anesthesia" we can obtain with ordinary ether, but with the difference that while primary anesthesia is very brief Cotton's analgesia can be extended several hours if need be.

When the administration of the new ether is pushed to the condition of surgical anesthesia, it does not differ greatly from that of ordinary ether

*The demonstration consisted in Dr. Hudson's charging a bottle type inhaler, of the pattern recommended by Dr. Cotton, with the new ether, and inviting the members to try it upon themselves. Three of them did so, while observations were made upon them by the others present. No difficulty was experienced in obtaining the analgesia described, those taking it carrying on an intelligent conversation meanwhile. In making the tests for sensation a wound was inadvertently inflicted upon one member which it was thought best to treat with an antiseptic.

In closing, Dr. Hudson asked those present not to confuse the new ether with the anesthesia ether being made by the DuPont Company, the latter being merely an ordinary anesthesia ether made according to the specifications of the U. S. Pharmacopœia.

except in relative freedom from after effects. It has one disadvantage, in that recovery from it is unusually quick, so that in two cases where it was used in this way, and the administration discontinued at the usual time at the command of the surgeon, the patient promptly returned to full consciousness before he could be sewed up. Personally, I believe that ethylene is not the only anesthetic carried in anesthesia ether, and that a little more research will disclose some deeper acting narcotic, which, when also added, will give a perfect ether for surgical anesthesia. But it is surely working in the right direction to add these substances in definite amounts to a perfectly pure ether, rejecting the harmful ingredients, now that we know that ordinary anesthesia ether is merely an accidental carrier of other substances.

OBSERVATIONS ON PYELITIS.*

By SAMUEL S. ROSENFELD, M.D.,

NEW YORK.

SURGICAL REGISTRAR, LEBANON HOSPITAL.

FROM the standpoint of diagnosis we are not as well acquainted with pyelitis as is popularly supposed. In proof of this assertion I cite the following: of 20,770 autopsies collected by Kapsmann of Vienna, pyelitis occurred 750 times and was correctly diagnosed during life in less than one-third the cases. Of the 50 cases I studied from the records of the Lebanon Hospital, the correct diagnosis was made by the family or admitting physician in six instances only, a percentage of 12. Of course, this low proportion of correctly diagnosed cases in hospital practice is due to the fact that cases recognized by the family physician are usually treated at home, the hospital receiving only the puzzling cases. But it is well known that pyelitis is in the majority of instances not recognized by most men before the third or fourth visit.

Pyelitis is defined by Osler as an inflammation of the pelvis of the kidney and the conditions which result from it. Cabot and Crabtree believe that the convoluted tubules are always temporarily involved in pyelitis, and have substituted the term pyelonephritis for what is usually known as pyelitis.

It occurs in all ages. Our youngest patient was three months old, and the oldest 46 years. In the hospital it is met with almost as frequently in the adult as in the pediatric wards.

From a study of the literature it seems evident that pyelitis is in nearly all cases due to bacterial invasion and multiplication. The kidney can usually eliminate bacteria carried to it, and becomes infected only when its resistance is lowered by some general or local cause. In this series among the important etiological factors were calculi, previous kidney disease, operations on the kidney, tuberculosis of the kidney, pregnancy, the puerperium, and associated with acute disease. These conditions are, of course, predisposing factors, lessening kidney resistance in one way or another. It is interesting to note the important part that pressure on the ureter plays in the latter half of pregnancy. Cruveilhier, in reporting autopsies in pregnant women, states that he found the ureters distinctly

dilated above the point of pressure. It usually occurs on the right side, which, according to Vineberg, is due to the fact that the gravid uterus and fetus more frequently occupy the right oblique diameter of the pelvis.

In cystoscopic examinations in cases of pyelitis of pregnancy, Pilcher found several instances of marked distortion of the vesical portion of the ureter. He believes that in the latter half of pregnancy pressure is the most important predisposing factor, and early in pregnancy the disease is due to toxic influences and hematogenous infection.

Several observers emphasize the association of pyelitis with gastrointestinal disturbances, especially in children.

The urine was cultured in ten cases, with the following results: Colon group, five cases; colon and staphylococcus, one case; staphylococcus, one case; streptococcus, one case; culture sterile, two cases. The percentage of positive culture was eighty. Cultures are now routinely taken and will undoubtedly show causative organisms reported by other observers, as the *Bacillus proteus*, gonococcus, and tubercle bacillus. French authors have called attention to the fact that bacilluria is present early; in many cases preceding the appearance of pus.

The mode of infection is given as: (1) ascending, (2) lymphatic, (3) hematogenous, (4) intestinal. Cabot and Crabtree conclude from their studies that the infection is hematogenous. Smith traces the course of infection thus: from the intestinal tract, or other focus of infection, the organisms enter into the lymph or even directly into the blood; from the lymph they pass to the blood, whence they are brought to the kidney, pass through the glomeruli and tubules, and are excreted into the pelvis.

The prevalence of the disease in females, the frequency with which the colon bacillus is found in culture and the proximity of the female urethra to the anus are held by Quinby and others to be strong points in favor of the ascending theory of infection.

Symptoms.—The symptoms are both local and general. In the acute cases, the local symptoms are usually of comparatively short duration, while they are more pronounced and continuous in the subacute and chronic ones. The usual case begins suddenly, with pain in one or both lumbar regions, ordinarily, however, one lumbar region. In a considerable number of cases the initial pain is experienced and often continues in the iliac or hypochondriac regions. There are chill, fever, sweat, nausea, vomiting, headache, nervous symptoms, the latter especially common in children; in fact, one child was sent to the hospital as a case of meningitis. Urinary disturbances are very common; frequent, difficult, or painful micturition is complained of either singly or together. In a few instances the patients noted cloudy urine or blood therein. In the majority of cases many of the above-mentioned symptoms are present, but in a considerable number, especially so in children and parturient women, only one or two symptoms of the most general nature may be present. Therefore, a routine microscopic examination of the urine is of vast importance.

The onset may be sudden or gradual. In this series it was sudden in two-thirds of the cases.

Pain.—The character of the pain varied; it was

*Read before the Lebanon Hospital Alumni Society, Nov. 17, 1917.

most frequently described by the patients, and qualified by several adjectives, as knife-like, stabbing, lancinating, and shooting; next in frequency came cramp-like, and then dull aching, especially in subacute and chronic cases. It was usually intermittent and of short duration in the acute, and rather constant and of long duration in the subacute and chronic cases. In over one-half the cases the pain started in the lumbar region; in four instances in both lumbar regions, but in three of them it rapidly subsided on one side and continued only on the opposite side. In thirteen cases the pain commenced in the iliac fossa, in five in the hypochondriac region, and in two in the epigastrium. In only six cases was there no transmission. The usual route of transmission was from the back to the pubic region, and in many cases it continued down the thigh. Transmission was also present in the opposite direction, *i.e.* from the iliac or hypochondriac regions to the back. In one case of chronic pyelitis the patient stated that she felt worse when thirsty and was relieved by drinking.

Chills.—The majority of the patients had one or more chills. A few only had chilliness; a small minority had neither chill nor chilliness.

The fever was in most cases remittent, although a considerable number showed the intermittent type. In some cases it rose several times to high levels after three to four days of practically normal temperature. Temperatures of 104° and even 105° were not at all uncommon, especially in children, nor was the septic type rare.

Nausea and Vomiting.—The great majority of the patients vomited, and most of them repeatedly.

Urinary symptoms were entirely absent in eight cases, although a considerable number commenced with urinary symptoms.

Bowels.—Constipation was the rule, although a considerable number had normal movements and four patients had diarrhea.

Marked nervous symptoms were encountered in four patients, ranging from symptoms of meningeal irritation to severe prostration.

Physical Signs.—The local tenderness in the lumbar region elicited by the Murphy or fist percussion, was of great diagnostic significance, especially in the acute cases. In the subacute or chronic the response, although present, was not as marked as in the former group of cases. In a few patients the kidney was palpable. In those cases in which iliac or hypochondriac pain was present, although tenderness was elicited, yet there was marked laxity of the abdominal muscles. This proved to be a very important sign.

Laboratory Findings.—The urine was almost uniformly acid, and contained from a faint to a moderate trace of albumin. Microscopically, the findings varied from a few white blood cells to abundant pus, red blood cells, and epithelial cells. On a few occasions pus was not found until the second or the third examination. In several instances pus urines were followed by clear urine, in turn to be followed by very cloudy, pussy urine. The bacteriological findings are given above.

In the blood count only the white blood cells and differential counts were of diagnostic importance. The average count was 15,000 and polymorphonuclear cells 78 per cent. The highest count was

30,000 (pyelonephritis having developed) and the lowest 6,000. In 23 cases the count was below 13,000. The onset of complications caused the counts to rise.

Diagnosis.—In arriving at a diagnosis of pyelitis one must remember that he is dealing with a disease which, especially in children, is likely to manifest itself by very few and quite general symptoms. Urinary examination is imperative, and even in infants all efforts should be made to collect and examine the urine. In male children it can easily be obtained by strapping a test tube about the penis; in females, massage and pressure over the bladder may be used and the urine caught in a waiting receptacle. If necessary, catheterization under sterile precautions may be resorted to. Pyelitis is easy to recognize when the characteristic symptoms, as chill, fever, vomiting, pain in the back with radiation, and pyuria, are present. On physical examination, a positive Murphy percussion sign and a lax abdomen, even if tenderness is elicited in the iliac or hypochondriac regions, is of marked diagnostic significance. An absolute diagnosis can be made only by examination of the urine, obtained by catheterization of the ureter.

Differential Diagnosis.—In making a differential diagnosis it will be interesting to note the diagnoses made by the family and admitting physicians in this series:

Acute appendicitis.....	8 cases	Not stated.....	6 cases
Perforating appendicitis,		Renal calculus.....	3 "
1 case		Intestinal intoxication,	
Pleurisy.....	1 "	1 case	
Pyelitis.....	6 cases	Gastroenteritis.....	1 "
Gastritis.....	1 case	Intestinal obstruction..	2 cases
Cholecystitis.....	4 cases	Meningitis.....	1 case
Ruptured ectopic		Asthma.....	1 "
pregnancy.....	1 case	Salpingitis.....	4 cases
Vaginal abscess.....	1 "	Sepsis.....	1 case
Nephritis.....	1 "	Typhoid fever.....	2 cases
Hematuria.....	1 "	Threatened abortion..	1 case
Vomiting of preg-		Menopause.....	1 "
nancy.....	1 "		

Thus it will be seen that one of the most important conditions from which we have to differentiate acute pyelitis is acute appendicitis. Both diseases have an acute onset, but appendicitis is rarely ushered in by a chill, while this is very common in pyelitis. Chills do occur in appendicitis, but only after the disease has lasted some time, and usually is indicative of abscess formation or rupture. This was the teaching of the late John B. Murphy. The pain in appendicitis usually begins in the epigastrium or about the umbilicus and radiates to and in a short time terminates by, a constant non-radiating pain in, the right iliac fossa. In several hundred cases I have never seen radiation down the thigh, although Schmidt in his treatise on pain states that radiation down the thigh does occur, though rarely, in appendicular colic. Lumbar pain and radiation to the inguinal region may occasionally occur with a retrocecal appendix. In the vast majority of instances, after appendicular pain has become localized in the right iliac fossa, radiation ceases. Initial fever in pyelitis is usually higher than in appendicitis and often shows a septic tendency, whereas in appendicitis it is usually more stable, rising with the increasing area or extent of infection. Of course, it is too dangerous to delay operation in a case of appendicitis to watch the temperature curve. Urinary disturbances are very common in pyelitis and uncommon in appendicitis, unless periappendicitis or peritonitis

has involved the bladder, a condition usually occurring late in this disease. A positive Murphy sign in the lumbar region is strongly in favor of renal or perirenal involvement, except in a very small percentage of retrocecal appendices, which sometimes give a positive Murphy sign when inflamed. Another good point in favor of pyelitis is flaccidity of the abdomen in the presence of iliac tenderness. The blood count, especially the polymorphonuclear count, is in the uncomplicated cases of pyelitis somewhat lower than in appendicitis, the former rarely going above 80 per cent., while in the latter it is the usual occurrence. In children, the polymorphonuclear count is in both diseases lower than in adults. While the urine in appendicitis may contain some pus cells, it presents in the main a fever picture. Of course, everything in medicine is possible, and both diseases may coexist occasionally. Gammeltoft of Copenhagen, in speaking of the differential diagnosis between appendicitis and pyelitis of pregnancy, states that cystoscopy does no harm even near term. It has been done in this hospital for differential diagnosis in borderline cases, but as yet there has been no occasion for it in pregnant women. Should cystoscopy still leave the condition in doubt, were I the patient I would prefer laparotomy rather than run the risk of neglected appendicular disease, with its possible gangrene, rupture, and peritonitis. Several surgeons and internists whom I have consulted have agreed with me in this respect.

Pyelitis must also be differentiated from other abdominal conditions, such as cholelithiasis and cholecystitis, salpingitis, etc. It is quite frequently mistaken for pneumonia. To sum up, pyelitis can be differentiated from other diseases by careful questioning, thorough and detailed physical examination, bearing in mind the value of Murphy percussion, the level at which it is obtained (usually at a lower level in pyelitis than in cholecystitis), and flaccidity of the abdomen in the presence of tenderness. Careful examination of the urine is, of course, paramount.

Prognosis.—There were no deaths in this series. Lately there have appeared several papers showing that the prognosis is not always favorable. The danger is pyelonephritis and pyonephrosis. Termination of pregnancy is not frequently necessary. Cragin believes that if symptoms continue and the child be viable interruption is indicated. Reed thinks that premature labor occurs in 50 per cent. of the cases. Ross of Toronto advises interruption of pregnancy if the symptoms are marked.

Treatment.—All observers agree as to the advisability of flushing. Water a plenty is the keynote of most therapists. In the drug treatment of the disease urotropin has come into almost universal use. Its action has been shown to depend on the liberation of formaldehyde, which it does only in acid media. Smith states that the best agent for making and keeping the urine acid is one-half teaspoon of acid sodium phosphate three times a day. Burnam has shown, and Jenner and Smith have confirmed his work, that with 5 to 10 grain doses of urotropin only two out of ten patients showed free formaldehyde in the urine. With 20 to 30 grains of urotropin over 60 per cent. of the patients showed formaldehyde. Many observers caution as

to the kidney irritation likely to be set up by urotropin and stop its use on the first appearance of red blood cells. Abt states that the dose in infants under one year ought not to exceed one grain and should be given in plenty of water. In adults the rational therapy seems to be moderately large doses, careful watching of the urine, and stoppage of urotropin on the first appearance of red blood cells. The scientific method would, of course, be to give that dose which would cause formaldehyde to appear in the urine. Formaldehyde can be tested for in the urine by one of several methods.

Jordan found that oleum santali has a selective action on the staphylococcus and none on the colon bacillus.

The alkaline treatment is based on the fact that the urine in pyelitis is in most cases acid. The alkalization is usually accomplished by administration of potassium citrate. In children, Freeman believes that the urotropin treatment is superior to the alkaline.

Quinby advocates the study of the causative organisms, especially as to their acid and gas production. He advises growing them according to the method of Clark and Lubs, and find the acid or hydrogen ion concentration in the medium. From this can be determined whether the acid or alkaline treatment is in order.

Postural Treatment.—Pilcher has shown that position is of great aid in treatment. He catheterized a patient in the sitting and in the lying positions, and obtained 4 c.c. in one minute when the patient was sitting and only 2 c.c. in ten minutes when the patient was lying. Elevation of the head and trunk and lowering of the pelvis afford drainage. Gammeltoft advises placing a pregnant woman on the side opposite to her lesion in order to relieve pressure on the affected pelvis.

Vaccine Treatment.—Reports as to the efficacy of vaccines differ. Cabot and Crabtree found that patients suffering from hypertrophy of the prostate, when treated with vaccines, developed no postoperative pyelitis; the immunity, however, is of short duration, and for the vaccines to be effective it must be continued throughout the convalescent period.

Local Treatment.—Pilcher obtained some very good results in pregnant women by washing the pelvis of the kidney with saline and injecting 40 to 50 per cent. solution of argyrol. Some men are using $\frac{1}{2}$ to 1 per cent. of silver nitrate for ureteral injection. In cases of marked pelvic retention Pilcher left the catheter in place for a few hours in order to get drainage. He reports good results. Gammeltoft, however, warns against washing out the pelvis, claiming that it may spread infection, and cautions against leaving the catheter in place, as hemorrhage may result. In pelvic retention, he claims that filling of the bladder often excites reflex ureteral contractions and may frequently give relief. He uses vaccines to ward off recurrences. Pilcher treats his cases medically for at least ten days before resorting to local treatment.

Quinby calls attention to the fact that in some cases of chronic pyelitis in children, especially females, cystoscopy and local treatment may be instituted with benefit. Cystoscopy is possible in children, although it should not be tried until the patient has had a good course of medical treatment.

To conclude the remarks on treatment, it is proper to say that medical treatment suffices in the vast majority of acute cases and that local and vaccine treatment are coming into their own in the chronic cases.

NERVOUS DISEASES OF SENILITY.*

BY M. NEUSTAEDTER, M.D., PH.D.,

NEW YORK.

LECTURER IN NEUROLOGY, NEW YORK UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

THE diseases of the cerebrospinal axis and the peripheral nerves in the aged may be classified as primary, namely, when the parenchymatous tissues are primarily and directly affected; or, again, as secondary, when due to changes in the vascular and lymphatic systems supplying the nerve tissues. These phases, however, cannot always be sharply separated from one another when we view the pathology of the neuraxis of senility in its macroscopic and microscopic appearance.

In normal old age the nervous system has undergone and still undergoes a process of slow decay. The brain shrinks, the cortical grey matter becomes thinner, and the fissures shallower, and this shrinking is compensated for by an increase of ventricular and subarachnoid fluids. In the spinal cord and peripheral nerves many of the medullary sheaths disappear. If these primary neuron changes become exaggerated, the condition becomes pathological and gives rise to the degenerative affections of old age.

This accentuation may be general or local, resulting in definite symptom complexes. This is also true of pathological conditions resulting from vascular changes.

According to Rokitsansky and others it has been established that the cerebral arteries are the ninth in the scale of frequency to be attacked. Macroscopically viewed the vessels of the brain are tortuous and irregular, their walls thickened, and their lumen proportionately diminished. Through extensive lime deposits these vessels become hardened tubes. On the inner surface they can be found as round, opaque, or yellowish elastic nodules, preeminently at points of bifurcation of the larger vessels or just where smaller ones branch off.

The histological picture of this change is that of a proliferating process in the walls of the vessels alongside regressive or inflammatory changes. The

*Read before the Yorkville Medical Society, January 21, 1918.

intima is irregularly thickened and its wavy regularity becomes lost and in places broken. Its endothelial cells may become loosened and float about. The loose elastic fibers proliferate and organize into a secondary internal elastic layer of a meshwork of fine fibers. Very few nuclei are found in it and no real round cell infiltration. The elastica interna frequently tears and gives rise to aneurysmal formation, although tears were noted without aneurysms.

The muscularis of such vessels may be atrophied and contain only a few nuclei or again may be hypertrophied and be rich in nuclei. In this coat one may find a diffuse or nodular proliferation of elastic fibers or again a loss or atrophy of pre-existing elastic fibers.

In the adventitia we find a proliferation of nuclei, especially in its outer layer. This nuclear augmentation favors certain localities, such as the angles of junction and of bifurcation. The Virchow-Robin-intra-adventitial spaces are as a rule distended and contain cellular elements and pigment. The proliferation of elastic tissue is here also evident. This is the picture of arteriosclerosis.

The changes in the veins are those of a fatty degeneration and a granular metamorphosis of the middle and inner coats. At times the adventitia is also involved. In old apoplectic foci one notices circumscribed or diffuse dilatations in the intra-adventitial lymph spaces. Here the changes are not as constant as in the arteries.

The perivascular lymph spaces are affected only in apoplectic and encephalomalic foci, where they are frequently dilated over five times their original size.

Alongside these changes we observe progressive and regressive trophic disturbances with true inflammatory changes in the inner and middle coats, giving rise to what is termed atheroma of the blood vessels.

Through such changes the lumen of the vessels may become diminished or entirely occluded; especially is this true of the smaller vessels. In the larger vessels a thrombus may form and ultimately occlude the lumen. The brain capillaries are rarely affected.

The disturbance of the circulation through such a narrowed or occluded vessel causes a deficient nutrition of the contiguous brain substance leading to encephalomalacia, while hemorrhages result from damage in the brittle vessel wall. Aneurysms, on the other hand, give rise to intracranial pressure and consequent degeneration of tissues. They may also burst when subjected to abnormal pressure from within and cause hemorrhages.

Symptoms resulting from such vascular states have often been mistaken for neurasthenia, hysteria, chronic meningitis, and even brain tumor.

Among the general symptoms are general muscular weakness, impairment or loss of memory, change of disposition, and mental irritability or even instability.

Among the special symptoms some have noticed a peculiar hyperesthesia in old people, not confined to the skin alone, but also caused by movement of any part of the body. Vertigo is one of the most distressing symptoms of chronic endarteritis. Grasset has divided this vertigo into simple vertigo,

vertigo with epileptiform crises, and vertigo with slow pulse and syncopal epileptiform attacks. The vertigo usually manifests itself as a sudden attack of nausea and faintness, a feeling of giddiness. The patient sees objects rotating about him, or a sudden darkness befalls him and a feeling of impending death. These attacks recur at intervals of varying duration and with varying degrees of intensity. When particularly severe, the patient may even fall, but consciousness is rarely lost.

When we come to consider special syndromes resulting from secondary changes of the brain tissues in arteriosclerosis the old rule holds good, namely, that they are entirely dependent upon the site of the lesion and not its character. And the extent of the symptoms is in direct ratio to the extent of the site involved. Thus an involvement of the motor area of the brain will give rise to spastic hemiplegias or diplegia and motor aphasia. If the sensory speech areas are involved we shall get sensory aphasias, such as word deafness or blindness and astereognosis. If both motor and sensory areas are involved, we get apraxia.

This rule also holds good in spinal cord involvements. The so-called senile paraplegia is the result of secondary cord changes, giving the picture of a transverse myelitis with lateral tract degeneration. Here we have a spastic paralysis of both lower extremities with exaggerated reflexes, clonus, and the Babinski phenomenon, and bladder and rectal sphincter involvement leading to either retention or incontinence of urine or feces.

A hemorrhage into one part of the cord gives rise to Brown-Séquard's syndrome, namely, a spastic paralysis in the leg on the side of the lesion and a loss of pain and temperature sense in the other. It is not unusual to see a case of central cord softening with paralysis and loss of pain and temperature sense in both legs. In this connection we may remember that various forms of tremors, choreiform, athetoid, and intention tremors are at times an accompaniment of hemiplegias.

Since most investigators consider Parkinson's disease an expression of premature senility, when occurring in the middle aged, we may be pardoned for including this clinical entity among the senile affections. Even those authors who oppose this hypothesis admit that vascular changes of this affection are analogous with those of senility.

Its pathological picture may be divided into four groups:

1. An endo- and periarteritis (arteriosclerosis) with secondary or simultaneous chronic inflammatory changes of the adventitial connective tissue and the neuroglia. Both these processes, which take place in the entire nervous system, central and peripheral, assume the greatest proportions in the cord in different degrees of intensity in different cases. Secondary changes in the cells of the cortex and basal ganglia, such as swelling, atrophy, accumulation of pigment, and amyloid bodies in the cell protoplasm, thickening of the glial septa in the cord, and closure of its central canal, the swelling of some nerve fibers and again atrophy of others is rather the common picture.

2. A primary alteration of nerve cells, be it of those of the anterior horns and of Clarke's column in the cord, or of those of the motor cortex of the

brain, or again of the Purkinje cells in the cerebellum without any apparent changes in the vessels or the connective tissue and the neuroglia.

3. Negative findings in the neurones, but changes in the muscular apparatus, namely, atrophy and fatty degeneration of the muscle fibers and a proliferation of their interstitial tissue.

4. Totally negative findings.

In view of the pathological findings and perhaps in spite of the lack of some pathological changes we have a symptom complex—the set facies, rigidity of the entire musculature, the characteristic non-intention tremor, the pill rolling movement of the thumb and index fingers, the stooping, bent posture, and the vasomotor symptoms—that speaks for senility; and when the condition occurs early in life, especially as a result of trauma and in train of a hemiplegia, as I have seen it, I am inclined to regard it as one of premature senility.

Senile epilepsy and senile chorea are in reality expressions of focal symptoms of arteriosclerotic changes, those of either encephalomalacia or slight hemorrhages, distributed over a large area and irritating the motor cortical or subcortical areas. Here we have, besides these symptoms, also paralyses or slight pareses limited to corresponding areas. There are also some speech defects, if the lesion involves the right brain hemisphere in right-handed people.

Senile polyneuritis, first described by Oppenheim, involves usually the spinal nerves and rarely the cranial. There is no definite etiology of this affection, although some authors have claimed arteriosclerosis as the base. Some have observed miliary carcinomatosis of the peripheral nerves. The disease begins insidiously, and is not accompanied by the usual intensely painful manifestations, as in multiple neuritis of the young. There is an increasing weakness and numbness in the extremities, followed by a progressive paresis. In some cases atrophy is associated with it and also quantitative electrical changes are present. The reflexes are abolished. In spite of their age these patients recover completely from this affection, if they do not succumb to brain hemorrhage.

The vasomotor-trophic neuroses, acroparesthesias, Raynaud's disease, erythromelalgia, and scleroderma have sometimes been seen to begin in later life, but, as this is of rather rare occurrence, it is needless to discuss these affections here.

Hysteria has been noticed in old age. All authors, however, warn us that it is usually a reappearance of an old condition or rather a state of an initial senile psychoneurosis. And here permit me to say a few words about senile psychoses.

The influence of senility upon psychoses depends upon the retardation of the functioning power of the brain cortex, that results from a pathologically intensified senile involution. This senile involution involves, on the one hand, the nerve elements directly, and again the vessels (arteriosclerosis), which disturb the nutrition of the cortex and indirectly damage the cortical elements.

The patients become egocentrically inclined, their ability to feel for the misfortunes of others, or even to comprehend them, becomes gradually lost. Their entire interest in life concentrates upon their own bodily needs and their own happiness. Their

productivity in the association of ideas is gone and they are unable to judge from analogies of past and present experiences. Their retentive memory is constantly becoming impaired, as is also their memory for recent events. In individuals with a psychopathic constitution, or those who during life were exposed to many diseases and therefore lost their power of resistance, various psychoses will flare up. These senile psychoses will attain the forms of a dementia, an hallucinatory or incoherent paranoia, melancholia, or an anxiety psychosis. All forms are accompanied by attacks of vertigo. Sometimes there are also pareses and paraphasias present in addition to other phenomena. The defective intelligence is a marked feature of all of them.

A special form of senile psychosis described by Alzheimer and named by the Germans presbyphrenia is characterized by a more or less uniform clinical and pathological picture. The disease begins with a gradual loss of retentive memory, disorientation, restlessness, delusions, hallucinations, transitory periods of confusion, paraphasia, and a gradually progressing mental weakening culminating in complete dementia and associated with general weakness, spasticity in the legs, and at times sluggish pupils.

The macroscopical pathological picture is that of a regional cerebral atrophy and arteriosclerosis of the smaller vessels and a dissemination of miliary plaques of necrosed tissue. Microscopically there is evidence of acute and chronic changes in the ganglion cells of the brain cortex and basal ganglia with a neuronophagocytosis. An extensive cell vacuolization is seen on preparations stained by the Bielschowsky method. There is a great loss of cells noticeable in the motor cortex, and those remaining are smaller than usual; they are filled with pigment, and the nuclei are eccentrically situated. A marked vessel proliferation in the subcortical layers is met with and no perivascular infiltration. We find there also a cellular and fibrillary gliosis, consisting of a large number of small elements and stellate cells. The Purkinje cells of the cerebellum are degenerated.

From the above remarks we might conclude that few diseases of the nervous system are limited to old age, as such, and when we peruse the literature we find that, with few exceptions, old age neither precludes nor especially favors the occurrence of central nervous disorders.

1215 PARK AVENUE.

Ethylhydrocuprein and Opticus Atrophy.—It has been definitely decided that this drug, as exhibited to pneumonia patients in even moderate doses, can cause organic disease of the optic nerve with permanent damage to vision. These accidents may occur in the midst of transitory and functional disturbances. Pincusohn, who saw only severe functional disturbances, simply cautions to limit the dose, but Schreiber, who reports three cases of permanent impairment of vision following a period of total blindness (hemeralopia, marked concentric diminution in visual fields), counsels control of vision by the subjective appearances (cobweb spectra, etc.) or slight mydriasis. These, Schreiber says, are danger signals which must be heeded.—*Archives Médicales Belges.*

HISTORICAL AND BIBLICAL DATA OF CIRCUMCISION.

By JOSEPH H. MARCUS, M.D.,

ATLANTIC CITY, N. J.

ATTENDING PHYSICIAN TO THE JEWISH SEASIDE HOME.

IN Biblical Hebrew, the word circumcision means "the cutting away of the foreskin."

Biblical Data.—A religious rite performed on male children of Jews on the eighth day after birth; also on their slaves, whether born in the house or not. It was enjoined upon Abraham and his descendants as "a token of the covenant" concluded with him by God for all generations, the penalty of nonobservance being "karet" (excision from the people). Aliens had to undergo circumcision before they could be allowed to partake of the covenant feast of Passover, or marry into a Jewish family. It was a "reproach" for the Israelite to be uncircumcised. Hence the name "arelim" (uncircumcised) became an opprobrious term, denoting the Philistines and other non-Israelites. In the minds of the ancient Hebrews it was deeply rooted that circumcision was an indispensable act of national consecration and purification. Nevertheless there are several facts in the Bible which do not seem to be in full harmony with this view. According to Ex. iv. 24-26, the circumcision of the first born was omitted by Moses, and the Lord therefore sought to "kill him"; whereupon "Zipporah took a flint and cut off the foreskin of her son, and made it touch the feet of Moses," saying, "A bridegroom of blood art thou to me." Thus Moses was ransomed by the blood of his son's circumcision.

Strange as was this omission on the part of Moses, the omission of the rite on the part of the Israelites in the wilderness was no less singular. As recorded in Josh. v. 2-9, "all the people that came out" of Egypt were circumcised, but those "born in the wilderness" were not; and therefore Joshua, before the celebration of the Passover, had them circumcised with knives of flint, at Gilgal, which name is explained as "the rolling away" of "the reproach of Egypt."

Attention has also been called to the peculiar attitude of Deuteronomy and the Prophets toward circumcision. Deut. x. 16 says, "Circumcise the foreskin of your heart," thus giving the rite a spiritual meaning; circumcision as a physical act being enjoined nowhere in the whole book. Jer. ix. 25, 26, goes so far as to say that circumcised and uncircumcised will be punished alike by the Lord; for "all the nations are uncircumcised, and all the house of Israel are uncircumcised in the heart." Obviously the prophetic view differed from that of the people.

Historical View.—Circumcision was known to be not an exclusively Jewish rite. Ishmael was circumcised when thirteen years old, that is, at the age of puberty. The rite was, in fact, practised not only in ancient Arabia but also in Ethiopia, as well as by almost all the primitive tribes of Africa, and many of Australia.

The accumulation of evidence points to the fact that circumcision in its primitive forms was connected with marriage, whether performed with the view to the facilitation of cohabitation, as Ploss thinks, or as is far more in accordance with the

psychology of all primitive as well as of all ancient nations, to the consecration of the generative powers. At all events the age of puberty is most frequently selected for the rite; and, after weeks of purification accompanied by tests of courage, the boy is formally graduated into manhood, and bearing a new name, is ushered into the bridal chamber. For Egypt the practise is attested not alone by Herodotus, Philo, and Ambrosius, but also by the monuments and the very valuable Greek text, published and discussed by R. Reizenstein.

The rite of circumcision signified admission of the boy at the age of puberty into the rank of priesthood, as "web" (the Egyptian for pure or holy), the mother's presence being considered especially necessary. In Biblical literature the ordinance is incidental to the recognition of heirship, and to the assumption of a new name. The neglect of Moses to circumcise Gershon was in all probability associated in some way with his (Moses') marriage to a Midianite woman. Zipporah, however, ultimately displayed her allegiance to the God of the Jews by performing the sacrament herself. The fact that in Arabic "hatana" denoted both "to marry and to circumcise" shows an original connection between the rite and the nuptial ceremony.

The critical view of the Pentateuch sufficiently accounts for the non-circumcision of young Israelites prior to their entrance into Canaan by the following theory: The ancient Hebrews followed the more primitive custom of undergoing circumcision at the age of puberty, the circumcision of young warriors at that age signifying the consecration of their manhood to their task as men of the covenant battling against the uncircumcised inhabitants. After the settlement of the Israelites in Palestine the rite was transferred to the eighth day after birth. In fixing the time of the initiatory rite at an age when its severity would be least felt, the Mosaic law shows its superiority over the older custom.

During the Babylonian exile the Sabbath and circumcision became the characteristic symbols of Judaism. This seems to be the underlying idea of Isa. 4: "The eunuchs that keep my Sabbath" still "hold fast by my covenant," though not having the sign of the covenant upon their flesh. Contact with Grecian life, especially at the games of the arena, made this distinction obnoxious to the Hellenists, or anti-nationalists; and the consequence was their attempt to appear like the Greeks by epispasm (making themselves foreskins). All the more did the law-observing Jews defy the edict of Antiochus Epiphanes prohibiting circumcision; and the Jewish women show their loyalty to the law, even at the risk of their lives, by themselves circumcising their sons.

In order to prevent the obliteration of "the seal of the covenant" on the flesh, as circumcision was henceforth called, the Rabbis instituted the "peri'ah" (the laying bare of the glans), without which the circumcision was declared to be of no value. Thenceforward circumcision was the mark of Jewish loyalty. To be born circumcised was regarded as the privilege of the saints, from Adam, "who was made in the image of God." Great importance was laid on the shedding of a drop of blood as a sign of the covenant when a child or a proselyte born circumcised was to be initiated into Judaism.

Uncircumcision being a blemish, circumcision was to remove it, and to render Abraham and his descendants perfect. He who destroys the covenant sign of Abraham (by epispasm), has no portion in the world to come. According to some, it was Shem who circumcised Abraham and Ishmael on the day of Atonement; and the blood of the covenant then shed is ever before God on that day to serve as an atoning power. According to the same authorities, Pharaoh prevented the Hebrew slaves from performing the ceremony, but when the Passover time came and brought them deliverance, they underwent circumcision, and mingled the blood of the paschal lamb with that of the Abrahamic covenant, wherefore repeats the words: "In thy blood live."

According to Sifre, the tribe of Levi was the only one that kept the covenant. They had piled up the foreskins of the circumcision in the wilderness and covered them with earth. To this Balaam referred when he asked: "Who can count the dust of Jacob?" and for this reason it became customary to cover the foreskin with earth. Talismanic powers were ascribed to the sign of the covenant, as also to the phylacteries. Agreeing to the Rabbinical story, David, when he saw himself at the bath stripped of the phylacteries and other religious insignia, thanked God for the Abrahamic rite protecting him, and sang the twelfth psalm, which bears the superscription "'Al-ha Sheminit" (lit., "on the eighth"), explained as referring to the rite of circumcision. Circumcision causes an angel to save the Israelites from the pangs of Gehenna (hell), to which, according to Ezek. xxxii. 24, the uncircumcised are consigned.

"Circumcision is one of the commandments which, having been accepted with joy, are ever obeyed with joy, and, because the people gave their lives for them, are observed with steadfast loyalty." This refers to the martyrdom which the Jewish people underwent during the Hadrianic persecution, which was especially directed against circumcision. "We ought to abstain from marrying," said R. Ishmael b. Elisha, "since the Roman government forbids us to celebrate the festival of the birth of a son; but then the world would come to a standstill."

"Why did God not make man as He wanted him to be?" asked Tinnius Tyrannus Rufus, with biting sarcasm; and Akiba replied, "In order that man should perfect himself by the fulfilment of a divine command."

In Gen. R. xlv. the arguments for and against circumcision are put forth in the form of a dialogue between God and Abraham. Replying to the question why the command had not been given to Adam, if it was so dear to Him, God reminds Abraham that it should be sufficient for him that he and God are in the world, and that the maintenance of the world depends upon the acceptance of the commandment. But Abraham objects in that circumcision is an obstacle to the conversion of the Gentiles. This trouble also is overcome by the declaration of God's sufficiency to protect both Abraham and the world. In fact, circumcision had been deferred from the time of Abraham's conversion—in the forty-eighth year of his life—until his ninety-ninth year, for the express purpose of facilitating the making of proselytes. The problem of proselytism, indeed,

had stirred Judaism to its very depths, and had almost separated Hellenistic from Palestinian Judaism. The story related in Gen. R. xlv. is as follows: King Monobaz and Izates, sons of King Ptolemy, read the book of Genesis together. When they came to the passage xvii. 11 they wept; and each without the other's knowledge underwent circumcision. The next time they read the chapter together one said to the other: "Woe unto me, my brother." Then they disclosed what they had done. Their mother on hearing of the matter, told their father that they had needed circumcision as a precaution against phimosis, and he signified his approval. As a reward for their action they were saved by an angel from being killed in an ambush during a war in which they had become involved.

The rigorous view of the covenant is echoed in the ancient Law Books: "If thy sons accept My Godhead (by undergoing circumcision) I shall be their God and bring them into the land; but if they do not observe My covenant in regard either to circumcision or to the Sabbath, they shall not enter the land of promise."

With the advent of the Roman wars, the more rigorous views became more prevalent everywhere. Thus Favius Clemens, a nephew of the Emperors Titus and Domitian, when with his wife Domitilla he embraced the Jewish faith, underwent circumcision, for which he suffered the penalty of death. It was chiefly this stern feature of Jewish proselytism which provoked the hostile measures of the Emperor Hadrian. And furthermore, it was the discussion of this same question among the Jews, whether the seal of circumcision might not find its substitute in "the seal of baptism."

While in Biblical times the mother (perhaps generally) performed the operation, it was in later times performed by a surgeon, also called by the specific name "mohel." In the Codex Justinianus physicians were prohibited from performing the operation on Roman citizens who had become converts to Judaism. Unlike Christian baptism, circumcision, however important it may be, is not a sacrament which gives the Jew his religious character as a Jew. An uncircumcised Jew is a full Jew by birth. A non-Jewish physician may, according to R. Meir, in the absence of a Jewish expert, perform the ceremony, as may women, slaves, and children. Circumcision must, whenever possible, take place on the eighth day, even when this falls on the Sabbath. It is the duty of the father to have his child circumcised; and if he fails in this, a certain official of the city must see that the rite is performed.

As early as the geonic time the ceremony had been transferred from the house of the parents to the synagogue, where it took place after the service in the presence of the whole congregation. In order to give it the character of a festival certain prayers of a mournful nature were omitted, and occasionally appropriate hymns were recited instead. In the tenth century there appears, in addition to the mohel and the father of the child, the godfather (sandek), who holds the neophyte on his knees during the operation. As a rule, the wife of the godfather carries the child in and hands it to the mohel, while the congregation greets it with: "Blessed be that which cometh in the name of the

Lord." Beside the chair upon which the godfather is seated, another chair is placed, called "the chair of Elijah." Upon this the mohel places the child, reciting Gen. xlix. 18; Ps. cxix. 156, 162, 166; and the first half of Ps. lxxv. 5, the congregation responding with the latter half. He then takes the child from "Elijah's chair" and places it upon a cushion in the lap of the sandek, reciting the benediction: "Blessed art Thou O Lord our God, King of the Universe, who has sanctified us by Thy commandments and hast enjoined us to perform the commandment of circumcision." When the operation is finished, the father of the child recites the benediction.

The abolition of circumcision in the case of proselytes, on the ground of its being a measure of extreme cruelty when performed upon adults, was proposed by Isaac M. Wise at the Rabbinical conference in Philadelphia in 1869, and was finally agreed to by the Reform Rabbis of America at the New York Conference in 1892.

Circumcision in Other Races.—The rite of circumcision appears to be both the oldest and the most widely spread surgical operation known. According to Andree, it is still practised by more than two hundred million people, which is quite a conservative estimate, since the followers of Islam alone are reckoned at two hundred and fifty million. Though not a principle or religious duty, it is spread throughout the Mohammedan world; consequently, both the age at which the operation is performed and the mode of treatment vary among Turks, Persians, Algerians, and Arabs. Among the Arabs circumcision seems to be a test of endurance. Philostorgius found it practised as early as 342 B. C. A much earlier instance, however, among Egyptian mummies is that of Amen-en-heb (lived between 1614 and 1555 B. C.), which one investigator has found to be a true case of circumcision. The practice extends over part of the Balkans, Asia Minor, Persia, part of India, and the Malay Archipelago, besides practically the whole of North Africa. Nor can this be due to Mohammedan influence, as it occurs quite as frequently among the tribes of the east and west coasts of Africa, which had not been in contact with Islam.

Even the Christian Abyssinians, the Bogos, and the Copts, the first of whom probably learned it from Jews, still observe the rite. Indeed, so universal is the practice in Africa that it would be simpler to get a list of the tribes that do not circumcise than to enumerate all those that do. The possibility of an Egyptian origin for circumcision is, however, completely disproved by the extent of the practice in Australia. The Australian evidence is of particular interest, the operation being performed there with a stone knife, as is recorded of the Israelites. The practice is almost equally widespread among the Islanders of the Malay Archipelago.

For America the evidence is somewhat scanty and relates chiefly to the central part of the continent, though Petitot reports the practice among the Athapascans, and McKenzie among the Dog River Indians. An analogous practice is reported by Squier among the inhabitants of Nicaragua, who draw blood from the organ and sow corn dipped in it. In Mexico a similar practice was found by

Cortez, according to the report of Garcia de Palacio (1576), but the blood drawn was offered at the altar. It is also reported among the Aztecs, the Mayas of Yucatan, the Caribs of the Orinoco, and the Tacunas of the Amazon, the Automecos, the Salivas, and the Guemos.

The possibility of this wide distribution of the practice being due to a dispersion from a single center like Egypt or Southern Arabia is disproved by the great variety of methods by which the removal of the prepuce is effected. The subject cannot be adequately treated without a reference to the analogous operation of clitoridectomy performed on nubile girls, sometimes accompanied by the so-called "infibulation" of the adjacent parts. This occurs among the S. Arabs in Egypt, in Abyssinia, among the Galoas, the Susus, the Mandingos, the Masai, the Waknosi (all of whom circumcise their boys), as well as in Peru and the banks of the Ucayale river. The operation is in nearly every case performed simultaneously, on males and females, though they are kept separate during the periods of preparation and operation.

One sect of Jews, the Falashas, also circumcise both sexes; it is probable that this practice has been adopted from the surrounding Abyssinians.

The instrument with which the operation is performed is in almost every case an ordinary knife of iron or steel; but as stated above, the Australians use stone knives, as the Jews and Egyptians did formerly, and as the North American Indians and the Abyssinian Alnajas still do. A case in which a stone knife was used by Jews is mentioned as late as 1726. Mussel shells are used in Polynesia. The Marolongs of South Africa use a fire-stone (meteorite), but now circumcise with an assegai.

Much variety is found in the age at which the rite is performed among different tribes. The earliest occurs among the Jews, on the eighth day after birth, and among the southwestern Arabs, who perform the ceremony on the seventh, fourteenth, twenty-first, or twenty-eighth day. The Susus near Timbuctoo and the Guemos of South America are also said to perform the rite on the eighth day. In East Africa the Mazequas perform it between the first and second month. The Persian Mohammedans circumcise in the third or fourth year; the Christian Copts, between the sixth and eighth. The Fijians perform the operation in the seventh year, as do also the Samoans. But apart from these instances, all the tribes who perform this rite do so at the age of puberty, which is, of course, a very significant fact.

The act of circumcision is generally accompanied by some special ceremonial. In Samoa it takes place when the youth is named; but most often it forms a part of the general set of ceremonies initiating the young of both sexes into mature life. This is generally accompanied by trials of endurance for the lads or young men; and from a certain point of view, circumcision may be looked upon as one of these tests, as is definitely the case among the Jauf of South Arabia (Halevy). As instances may be mentioned the elaborate ceremonials of African and Australian savages; but there is nothing specifically religious in the initiation ceremonies, the elders of the tribe performing the operation and instructing the neophytes. Among the Falashas, three old women perform the rite,

possibly because it is practised upon girls as well as boys. Occasionally the operation is performed by the priest; and in the New Hebrides a distinctly mystic character is imparted to the ceremony, no woman being allowed to be present.

Similarly, Livingstone found it impossible to obtain access to the "boguera" of the Bechuanas. Among the Bourana the lads are kept apart in a special hut, and on the day of circumcision an ox is sacrificed, and all smear themselves with its blood. Among the Sulus the blood is received in a cup of ashes and buried, while with the Maralonges the removed foreskin is buried. The rite is mostly common to the whole population, but occasionally, as in Rock Island, it is performed on the rich only, while in Celebes it is only resorted to in the case of princes who have no children. In Mexico it seems to have been a prerogative of the upper classes. There are certain indications which seem to show that primitive peoples adopt or drop the practice without much ado, possibly because it is not regarded as definitely religious. The Zulus and the Gallas have discarded the custom since Europeans have become acquainted with them.

The exact object for which this widespread custom is practised has been long a subject of dispute. The theories mainly held point to three originating causes: tribal, sacrificial, and utilitarian. For the tribal view there is to be said that circumcision, like other mutilations of the body intended for tribal marks, takes place at the age of puberty, when, for example, the Hereros of Africa knock out the front teeth; but as the organ is almost invariably hidden, it is difficult to see how circumcision could be regarded as a tribal mark.

The sacrificial theory, which sees in circumcision an offering to the deity of fertility, has to draw for illustration from the practices of Yucatan and Nicaragua, where the custom itself is only in a stage of survival, if it exists at all. Others regard it as a substitute for human sacrifice, and place it on the same level as eunuchism. Hence Herbert Spencer suggests that it was a mark of subjection introduced by conquering warriors to supersede the punishment of death. The appeal made to Samson by his father, and that made to the Israelites and to Saul by David, give a certain amount of plausibility to this theory; but the fact that the practice is either common to all the tribe, or is reserved for the upper classes, as in Mexico, the Celebes, and Rock Island, tells strongly against this last form of sacrificial theory.

The suggestion of Sir Richard Burton that it was introduced to promote fertility seems to be contradicted by the practice and arguments of many tribes. The claims of cleanliness and health have been strongly urged, especially for hot countries, where phimosis is likely to be induced if the natural secretions of the parts are retained by the prepuce. Philo gives this as one of the motives for the Biblical injunction. But the practice is found among so many tribes who have not the most elementary notions of cleanliness, not to speak of hygiene, that this is not likely to be the prevailing motive for its adoption. The fact that circumcision is almost invariably found practised as a rite of initiation, and frequently on both sexes, gives the clue to its general adoption. According to the wise custom among savages of initiating their youth into all

the duties of mature life, the elders prepare the lads for their marital life at this time; and circumcision, often of both sexes, is resorted to as part of the preparation. The only ancient legend about Zipporah circumcising the son of Moses confirms the view to some extent; but the exceptionally early age at which Jews perform the rite takes it entirely out of the category of initiatory ceremonies among them, and proves it to be of a religious or symbolic nature, as indeed is expressly claimed for it.

Circumcision varies considerably as practised by the Jews and by the Mohammedans. Among the Jews it means not only the excision of the outer part of the prepuce, but also a slitting of its inner lining to facilitate the total uncovering of the glans. The Mohammedans pursue the simple method of cutting off the integumental portion of the foreskin, so that almost all of the inner layer remains, and the glans continues covered. The operation up to recent times was exclusively performed by laymen, to whom the act has been taught by others who, by experience, had acquired the necessary knowledge and skill. The tests of a good operator, or mohel, were that he should perform the work quickly, safely as to its immediate effect, and successfully as to the condition which the parts would permanently assume. As a rule the majority of these operators developed great dexterity, and the accidents were remarkably rare. In case the glans was not sufficiently exposed after the healing process was completed, much anxiety was occasioned, for in some exceptional instances a second operation was resorted to. The operation consists of three parts: "*milah*," "*per'iah*," and "*mezizah*."

Milah: The child having been placed on a pillow, resting upon the lap of the godfather, the mohel exposes the parts by removal of the garments, etc., and instructs the godfather how to hold the child's legs. The mohel then grasps the prepuce between the thumb and the index finger of the left hand, exerting sufficient traction to draw it from the glans, and places a shield in position just before the glans. He now takes the knife and with one sweep excises the foreskin. This completes the first act. The knife most commonly used is double edged, although one like those ordinarily used by surgeons is most often employed.

Per'iah: After the excision has been completed the mohel seizes the inner lining of the prepuce, which still covers the glans, with the thumb nail and index finger of each hand, and tears it so that he can roll it fully back over the glans and expose the latter completely. The mohel usually has his thumb nail suitably trimmed for the purpose. In exceptional cases the inner lining of the prepuce is more or less extensively adherent to the glans, which interferes somewhat with the ready removal; but persistent effort will overcome the difficulty.

Mezizah: By this is meant the sucking of the blood from the wound. The mohel takes some wine in his mouth and applies his lips to the part involved in the operation, and exerts suction, after which he expels the mixture of wine and blood into a receptacle provided for the purpose. This procedure is repeated several times, and completes the operation, except as to the control of the bleeding and the dressing of the wound. The remedies employed for the former purpose vary greatly among

different operators and in different countries. Astringent powders enter largely into these applications. In North Germany the following mixture is extensively used: dilute sulfuric acid, one part; honey, two parts; and vinegar, six parts. A favorite remedy with many operators is the tincture of the chloride of iron, which is a recognized efficient styptic.

These solutions are applied by means of small circular pieces of linen with openings in the center, into which the glans is placed, and the dressing is closely applied to the parts below. This is secured in its place by a few turns of a small bandage. A diaper is now applied and the operation is finished. The dressings are usually allowed to remain until the third day. The nurse in the meantime is instructed to apply olive oil, plain or carbolyzed. When the parts are then uncovered, the wound will in most cases have healed.

To guard against any mishap through suppuration or erysipelas, the genitals are washed with soap and water, and afterward with a solution of bichloride of mercury, 1 to 2,000. The mohel deals in a similar manner with his hands, and especially with his nails, using a nail brush; and all the instruments that are to be used are immersed in boiling water for five minutes. The dressings consist of plain or antiseptic gauze, or similar material. All the preparations relating to the dressings, the instruments, and the hands, should be made before the child is brought into the room in which the operation is to be performed, in order to avoid unnecessarily prolonging the anxiety of the mother. A basin with the bichloride of mercury solution is always at hand, so that the operator may dip his hands immediately before he begins his work.

Some operators dispense with the shield, but this is not recommended, for it will expose the child to the risk of having a piece of the glans cut off, and to dangerous bleeding in consequence. When the mohel uses his nails to tear the inner layer (*per'iah*) he should be careful to have them absolutely clean. Should they not have the requisite shape or firmness, or should he prefer avoiding any risk attaching to that method, two pairs of short forceps may with advantage be substituted, and are now often used. The tear should be made carefully, so that it will not deviate greatly from the median line, and should not be carried back too far; for at the margin of the corona it might give rise to unnecessary bleeding. When the inner lining is tough, or bound down by adhesions, a probe-pointed scissors may be used for the *per'iah*. Some Hebrew scholars recommend the use of the scissors in all cases, claiming that the wound made by them is more favorable and infection less liable. Against this, however, is the well-established principle in surgery that a lacerated wound is less apt to bleed than one made by a sharp instrument.

Considerable opposition has in late years been made against the *mezizah*, on the ground that it is entirely in conflict with the aseptic treatment of the wounds, which should be adhered to in all instances, but more especially in consequence of the case in Cracow, in which it became known that syphilis was communicated to a large number of Jewish children through an affected condition of the mohel's mouth.

The result has been that a number of mohels have discarded the sucking of the wound altogether. The majority of Jews, however, remain averse to such an innovation, the more so because it is condemned by the Orthodox rabbis. As a compromise, which has received the ecclesiastical authority, a method has been adopted which consists in the application of a glass cylinder that has a compressed mouthpiece, by means of which suction is accomplished. Before the cylinder is applied a small quantity of sterilized absorbent cotton is placed in the mouthpiece, which effectually protects both the child and the operator.

The mohel should remain with the child for at least an hour, to be perfectly satisfied that no hemorrhage follows, and to stop it when it occurs. If the bleeding does not proceed from an artery, the tincture of iron, with somewhat firmer pressure of the bandage, will usually prove satisfactory. Should the bleeding come in jets, an artery forceps must be applied, and a surgeon should be sent for, as a ligature may be needed.

There is one form of bleeding which has thus far not been mentioned and which needs consideration. It is well known that there are individuals who bleed very profusely and very persistently upon the slightest provocation. The old rabbis must have known of this condition, for they taught that, a mother losing two children from circumcision, those that might be born afterward should not be subjected to the operation. This dangerous condition we know now as hemophilia.

It happens not infrequently that the attending physician, on account of some unfavorable condition of the child, advises a postponement of the operation. The Jewish law sanctions such a proceeding until the child has fully recovered its health. The following reasons for postponing the operation are enumerated by some as follows: pronounced feebleness of the child, febrile conditions, obstinate diarrhea, refusing to take the breast, diseased conditions of the skin, general or local convulsions or jerkings, inflammation of the eyes or eyelids, fungus excrescences in the mouth, very frequent vomiting, and continued sleeplessness.

Circumcision among the Jews has been accepted and adhered to simply as a religious rite; of the advantages of circumcision nothing shall be mentioned by me, for we are all well aware of this phase of the question.

Among the Arabs.—It is difficult to determine whether Mohammed deemed circumcision to be a national custom of no religious importance and therefore did not mention it in the Koran, or whether he judged the prescription of a rite that had been performed by the Arabs from time immemorial to be superfluous. Being as it may, circumcision became in Islam a religious obligation to which everyone was required to submit.

The difference of opinion which prevails among historians and traditionalists as to the character of the rite before Mohammed prevails also as to the age at which circumcision had to be performed. According to Josephus, the Arabs circumcised after the age of thirteen, because Ishmael, the founder of their nation was circumcised at that age. The Mohammedan law recommends circumcision between the ages of seven and twelve years, but it is

lawful to circumcise a child seven days after its birth. The circumcision of females is also allowed and is commonly practised in Arabia. The operation on males is generally performed by a barber, in the following manner: the operator seizes with the forefinger and thumb of the left hand the summit of the prepuce, which he fastens with a string provided with a knot. This string is passed through a hole made in a disc of hardened leather. The operator then makes with a razor or scissors a circular section of the prepuce between the knot and the disc. The hemorrhage which follows is stopped by the application of burned rags and ashes. In India a bit of stick is used as a probe and carried round and round between the glans and prepuce, to ascertain the exact extent of the frenum, that no unnatural adhesions exist. No splitting is known to the Arabs, as attested by Simon ben Zemah Duran, who expresses himself as follows: "Mohammed sanctioned also circumcision that the Arabs performed since the time of Abraham, as is said in one of the ancient law books of the Jews: 'A circumcised Arab'; but he adopted it without *peri'ah*."

The ceremonies preceding circumcision give to this act the character of a religious initiation. After having performed the prescribed ablutions, the candidate makes his confession before the imam, and a new name is added to his former one. As among Jews, circumcision is followed among Mussulmans by feasting and rejoicing. The custom among Jews in Russia and Poland of inviting pious men to spend the night preceding circumcision in prayer and study in the house in which the ceremony is to take place, finds a striking parallel in that current among the Mussulmans of Egypt. Here priests are hired to recite prayers in the house of the candidate the night before the ceremony. That night is called "*lailah al-kabirah*" (the great night), in opposition to the preceding night, "*lailah al-saghirah*" (the small night), in which an entertainment is given to friends.

A few words relative to "Elijah's Chair," previously mentioned: At every circumcision Elijah, "the angel of the covenant," as he is called, is supposed to be seated at the right hand of the godfather, upon a chair richly carved and ornamented with embroideries. Even in the salutation to the child to be circumcised is read the invitation to Elijah.

When under the influence of Jezebel, circumcision in the northern kingdom was about to be abolished, Elijah is said to have retired to a cave. There he prayed to God and complained that Israel had forsaken the covenant of the Lord; whereupon God ordained that no circumcision should take place except in the presence of Elijah. Some consider this to be a commendation of Elijah for his zeal; others, again, take it to be a measure of protection for Israel, in that Elijah is in every instance to be satisfied that the covenant is not being broken. Accordingly the ceremony demands that a distinct seat upon the bench, or a separate chair, be reserved for Elijah. To this the circumciser refers in the prayer preceding the circumcision. When the chair of Elijah is made ready, the words "This is the chair of Elijah" must be said in a loud voice. Before the circumcision takes place, the child is placed on the chair. The chair is left in position

for three days, not, as said by some, to give Elijah, the wanderer, time for rest, but because the first three days after circumcision are a period of danger for the child.

Elijah being the guardian of the little ones, is represented as such in the amulet for the lying-in chamber, and, indeed, it is in this capacity that he is invited to the circumcision.

In Regensburg, R. Judah the Pious was once entrusted with the office of godfather. The child was brought in and greeted by all with the customary formula, but Judah remained silent. Being questioned, he said: "I do not see Elijah seated at my side." As he said this a venerable old man appeared at the window, and to him he referred the questioners. To them the old man declared that Elijah refused to come because the child would one day abandon the faith of his forefathers. The prophecy was fulfilled.

One authority's work deals with the objection that Elijah could not possibly be present at different circumcisions at the same time. As the sunlight and the Angel of Death are omnipresent, so can Elijah be.

521 PACIFIC AVENUE.

Medicolegal Notes.

Malpractice—Childbirth—Question for Jury.—In an action against a practising physician employed to attend a married woman in childbirth it was charged that the death of the new-born child was due to the negligent acts and omissions of the defendant. From a judgment for the defendant the plaintiffs, the mother and her husband, appealed. The evidence on their behalf tended to show that the wife, being about seven months advanced in pregnancy, was suffering pains and the defendant was summoned to attend her. He arrived about half an hour after the summons and found a nurse already in attendance. After making an examination of the patient, he stated that the water would break in half or three-quarters of an hour, and that a rubber sheet should be placed on the bed. The patient was made to lie down on the bed and was told to remain very still, and the nurse was instructed not to help her. After spending fifteen or twenty minutes with the patient, the defendant departed, saying he would return in half an hour. The defendant did not return until after the lapse of nearly an hour. The water broke within half an hour after his departure, and the baby was born about four or five minutes thereafter. At the time of birth the nurse was holding the patient's hands, but released them to pick up the child, which was apparently face downward upon the bed. The child was apparently normal and fully developed for its period of pregnancy, of about six pounds weight, and uttered a natural cry shortly after delivery, but soon began to choke and froth at the mouth, at the same time becoming black in the face. The child died in about five hours, during which period the nurse tried various methods of assuaging its sufferings. The defendant returned to the house about half an hour after the birth, noticed that the baby in the hands of the nurse was frothing at the mouth, told her to wipe the froth from its mouth quickly, stated that he thought the child would not live, and then passed to the mother's bedside. Whether the defendant took any measures for the child's relief after assuring himself of the satisfactory condition of the mother did not appear from the evidence. The nurse had the child in the room adjoining that occupied by the mother, and the latter testified that she did not know what was being done in the room. The nurse was not called as a witness, and the husband left the house for his work within ten minutes after the defendant's arrival. The only evidence as to death being due to strangulation was the testimony of the mother that "she supposed it sucked its lungs full of water," on which testimony her cross-

examination was as follows: "Q. Isn't it a fact that she [the nurse] had difficulty in trying to get the child to breathe? A. I suppose so. * * * She hit it on the back and tried to get it to breathe after it was born. Q. What was the matter with it when she tried to pat it on the back? A. I am almost sure it drew water on its lungs; when it cried it went to strangling. Q. Did it cry when she picked it up? A. No, sir; it was strangling just like any baby drawing water down its throat. Q. Did you actually see the child have its face in the water? A. No, I didn't actually see that; I suppose that is what—what would it strangle for if it wasn't?"

The evidence showed that there was no rubber sheeting to catch the water from the breaking sac; that the water was discharged upon the ordinary bedding of sheet, quilts and mattress. There was no proof of water thereon in sufficient quantity to be drawn into the lungs, other than arose from the inference to be drawn from its having been discharged thereon, which was met by an equally possible inference that it had soaked into the bedding. The showing of death as having resulted from drawing water into the lungs was held not to arise above the merest surmise. On the other hand, an expert who was introduced by the plaintiffs testified that the death of the child, according to the symptoms in evidence, might have been due to any one of the other means. It was held that there was not sufficient evidence to warrant the submission of the case to the jury.—*Henline v. Southward*, Washington Supreme Court, 199 Pac. 315.

Agreement Not to Practise in Locality.—The Kansas City Court of Appeals holds that a verbal contract whereby one physician sells his house and practice to another and agrees not to practise medicine in the future within a distance of ten miles is not invalid as not being supported by a sufficient consideration; refraining from further practice in the territory designated being one of the effective inducements to the purchase of the house. Where such a contract was carried out by making a conveyance of the house, the deed reciting nothing in relation to the agreement concerning the medical practice, in a suit for an injunction to restrain the seller from practising medicine in the designated territory, parol evidence of such verbal contract was held not inadmissible as varying a written contract, the written conveyance not purporting to contain all the terms of the parol agreement.—*Scott v. Asbury* (Mo.), 198 S. W. 1131.

Hypothetical Questions.—In an action for injuries received in an assault the attending physician was asked whether, if the plaintiff's ear was filled with dirt, gravel, and mud, that would not be the most probable way of having germs introduced. The physician answered the question entirely on his personal observation and not upon hypothesis. It was held that the answer was entitled to be considered by the jury for what it was worth and should not be stricken out on the theory that the question and answer were not hypothetical. A medical expert may testify that from his personal examination he knew a person was deaf. While it is the better practice to reduce a hypothetical question to writing, where the facts are confusing and complicated, the allowance of an oral hypothetical question, based on previous questions, amendments, objections and colloquy, which covered four pages of the record, cannot, it is held, be treated as reversible error. Where the court charged that before a hypothetical question and answer could be considered the jury must find that the condition as stated in the hypothetical question was proven by a preponderance of the evidence, the overruling of an objection that a hypothetical question did not set forth all the assumed facts relied upon, and that to supply the deficiency counsel assumed all facts stated in a previous hypothetical question, was not reversible error.—*Matthews v. Lamberton*, Michigan Supreme Court, 165 N. W. 748.

"Accident"—Loss of Sight.—The Kentucky Court of Appeals holds that loss of sight in an eye from embolus due to the insured's general condition, but possibly aggravated by his intentionally lifting goods, is not covered by a policy insuring against injuries sustained through accidental means, and resulting, exclusively of other causes, in disability.—*Salinger v. Casualty & Fidelity Co.* (Ky.), 198 S. W. 1163.

Military Medicine.

FRACTURES OF THE JAWS FROM PROJECTILES.

RIFLE and shrapnel bullets, causing lesions of the jaw bones, given their rounded and smooth surface, usually do not produce splintering or other severe disorders, but the same cannot be said of bursting shell, which, when the pieces are of any considerable size, may carry away an entire portion of the facial block. The projectile may hit the jaw either in a transverse direction by passing through one cheek to the other, and this is perhaps the most frequent occurrence of all, or it may strike over one of the nasal fossæ and, according to its momentum, remain embedded in the spine or make its exit on one side of the neck. Missiles have been known to pass through the cheek from in front backwards, fracture the upper jaw and the ascending ramus of the lower jaw, and then become arrested in the parotid space. They may likewise become simply lodged in the maxillary sinus, after having perforated the anterior wall of this cavity. No matter what may be the point of penetration of the projectile, the lesions encountered in the jaws are perforation or splintering or partial fractures with or without loss of osseous substance. Such fractures are *direct*, that is to say that they occur at the point hit by the missile.

The diagnosis can in most instances be made by the clinical signs presented. Radiography of the upper jaw, unless the case be one of fracture of the alveolar process, or intrabuccal radiography of the palatine vault, gives very indistinct results, and therefore is most unsatisfactory. The gravity of these fractures depends almost entirely upon the concomitant lesions, such as communication between the fracture focus and the surrounding cavities, the orbit, sinuses, and cranium. But what is most important and never to be lost sight of is that the missile may provoke and maintain a focus of suppuration. On the other hand, the projectile may involve certain regional vessels or nerves, or the parotid gland itself.

Secondary deformities should also be mentioned, due to a loss of bone substance or to cicatricial contraction of the cheek, but it is an easy matter to fill in the loss of substance by means of a prosthetic apparatus or bone graft. As to facial deformities, they are often amenable to plastic operations, the results of which are sometimes truly marvelous. The treatment of maxillary fractures is both surgical and prosthetic. Surgery assumes the responsibility of replacing the fractured fragments in proper position, because apparatuses of correction of the deformity act with intolerable slowness, and, it may be added, are uncertain in results. Prosthesis maintains the fragments in position, once reduction is accomplished.

Treatment of Syphilis from the Military Viewpoint.—Dujardin (*Archives Médicales Belges*, December, 1917) discusses the exclusively mercurial, exclusively arsenical, and mixed plans of treatment. The two first named have but few advocates and thus largely eliminate themselves. However, in the mixed treatment arsenic may

monopolize our resources for a considerable period, and this is true especially of military practice. The exigencies of the latter often appear to justify attempts to abort the disease in its earliest stages, but we must face the fact of arsenic toxicity; whence the concerted effort throughout the world to learn the maximum safe dose. It is agreed that 90 centigrams of neosalvarsan given intravenously is the largest safe single dose for a man (75 centigrams for a woman). This should not be given at the outset, but led up to gradually. The author would begin with a dose of 30 cgm. and add 15 to each successive dose until 90 is reached. All important is the spacing. It is claimed that under a neosalvarsan cure 45 cgm. is eliminated every 2 or 3 days. The spacing, however, must not be so wide that the drug has a chance to leave the body completely. The spirochete must be crowded—given no rest; hence the following scale is suggested: First day, 30 cgm.; third day, 45 cgm.; seventh day, 60 cgm.; twelfth day, 75 cgm.; eighteenth day, 90 cgm. Of such a cure it is expected that every contagious lesion will be removed so that the patient will not be dangerous to his entourage. The serious and fatal accidents of the neurorecidive type should not develop after a cure of this sort, but in a certain percentage of cases unpleasant symptoms may develop some months after completion of the cure. Should intravenous injections of mercury be superadded to these rapid salvarsan cures? No other form of exhibition would satisfy military needs. Some army surgeons use 15 mgm. of the cyanate between the salvarsan injections and for some time afterward, until 10 or 15 injections have been given. It seems prudent to others to hold back mercury until a later period.

The author has treated 731 syphilitics during the war. All important is the subject of the contagious recrudescence. Of 338 cases, mostly of contagious syphilis in garrison troops, controlled for over a year, but 6 showed this kind of relapse (2 per cent.). These subjects required an average of 20 consecutive days of hospital sojourn, all subsequent visits being ambulatory. This material was, of course, selective, for the troops were stationary. The exact medication does not appear in the author's summary. In a series of 180 syphilitics put in condition for a return to the front the author probably combined salvarsan and mercurial injections, but separate statistics are lacking.

In addition to these cases, numbering 518, the author treated other patients to make up the total of 731. The numerous accidents recorded by him are not grouped, and we only learn that one subject died as a result of treatment, while numerous accidents occurred either because of or in spite of the treatment. The author believes that a sterilizing treatment which does not sterilize is responsible for a series of accidents which would not have occurred from the natural evolution of the disease alone. Chief among these is the meningeal syndrome, with changes in the cerebrospinal fluid and occasional paralysis of the cranial nerves.

The Strain and Stress of War.—That the war in

Europe has been responsible for a large number of cases of functional nervous disease can scarcely be a matter for surprise to members of the medical profession. For some considerable time the tendency to neurotic manifestations has been on the increase among the male population of all highly civilized and industrial countries, and when an individual of this type has been subjected to the added stress and strain of modern warfare it is not surprising that sooner or later he should break down under the excessive pressure.

Col. Sir John Collie delivered in London some time ago an address on this subject (*Recalled to Life*). He pointed out that approximately there were 34,000 men in Great Britain who were drawing pensions because of their inability to serve on account of some functional nervous disease. Such men were by no means necessarily cowards, indeed many of the 34,000 had distinguished themselves by signal acts of bravery and when seemingly recovered many had expressed a wish to return to the front, were impelled thereto by a sense of duty. Of course they could not go because they were temperamentally and neurotically unfit for the work. The time for presenting these nervous breakdowns is, if possible, before the acceptance of the man in the army. There are a large number of men apparently physically fit who exhibit no symptoms which would justify the medical examiner in rejecting them, and who yet will "crack" under the nerve-racking and emotion-straining experience of war as it is waged today. It has been announced recently that the Medical Department of the U. S. Army has decided to extend its psychological examination to all enlisted men and to all newly appointed officers of the army. The extension of this form of examination is due to the success which has attended the experiment of psychological examination made at Camps Lee and Devens. The purposes of the tests as outlined by Major Robert M. Yerkes in charge of the section of psychology of the surgeon general's office, are as follows: (1) To aid in segregating and eliminating the mentally incompetent. (2) To classify men according to their mental capacity. (3) To assist in selecting competent men for responsible positions. This decision of the War Department is a step in the right direction, and may aid in solving the problem of the neurasthenic drafted man, although there is little or no relation between mental deficiency and neurasthenia. The existence of an obvious tendency to functional nervous disease should be easily detected by a careful examiner, but it is extremely difficult, in fact impossible in the majority of instances, to diagnose a simple predisposition to neurasthenia. Therefore a large number of cases of shock will continue to be returned from the front and the object must be to treat these as efficiently as possible.

Sir John Collie, in the lecture above mentioned, says that medical treatment is of no real value unless the medical men have confidence in themselves and can commandeer the confidence of the patient. Infinite patience, common sense at every turn, and real, but thoroughly disguised sympathy are essential in those who undertake the care of

such cases. Massage, electricity, persuasion, occupation, light, graduated work, fresh air, good wholesome food, and above all a healthy environment are essential adjuncts. The psychotherapeutic method of treatment has been found by experience to be wonderfully effective provided only that it is in the right hands. Nothing retards recovery so much as the flying visits of unthinking, but kindly intentioned philanthropic lady visitors. Persuasive conversation should be systematically arranged for, in which the patient and doctor can have quiet talks, so that the man is led by tact and guarded sympathy to lay bare, what is, as it were, at the back of his mind. Nothing in the nature of psychoanalysis, however, is recommended. Collie's experience is that it is better that all patients should be isolated during the early part of their treatment. The calm restfulness of solitude has a peculiar effect in allaying irritability, and strange as it may appear, prevents morbid introspection. Isolation is not solitary confinement, a nurse is in frequent attendance. The short initial stage of isolation enhances the value of the suggestion of rapid recovery practised by the physician and nurses. Electrical treatment for these cases is of value, but the stoutest advocates of this method will not deny that the effect is intimately associated with the mysteriousness of the electric current. There is one proviso to make with regard to all treatment and that is, unless the patient desires to get well no treatment can cure him.

Regulations for Next Army Draft.—Revised instructions have been sent from the Surgeon General's Office to the medical advisory boards throughout the country reclassifying the drafted men according to their physical condition. The new regulations provide that every man summoned before the board shall be placed in one of the following four classes: (A) Acceptable for general military service. (B) Acceptable for general military service, after being cured of remedial defect. (C) Acceptable for special or limited military service in a specified capacity or occupation. (D) Rejected and exempted from any military service.

The Provost Marshal General announces his intention to provide later for the further investigation and classification of the men acceptable for limited or special service. Many ailments and defects that gained exemption of drafted men in the past now will result only in their being listed in Group B. Such men if they choose will be given the privilege of securing the services of their family physician to remove their defect. If they do not avail themselves of this privilege within a specified time they will be called into military service and ordered to a cantonment base hospital, a reconstruction hospital, or a civil hospital.

Health of American Forces in British Waters.—A report from the base of the American Flotilla in British waters announces that there has been but one death from disease in nine months among the American forces in the destroyers and supply ships operating from this base. This excellent report is regarded as a splendid tribute to the flotilla's senior surgeon and his two assistants. During this period 62 operations under general anesthesia have been

performed, the majority of these being abdominal operations. In all of these operations there was not a single case of infection. During the same period there were 189 minor operations, performed under local anesthesia. The medical work consisted chiefly in the care and treatment of respiratory disease due to exposure to inclement weather.

Football Players Make Poor Soldiers.—A prominent Glasgow physician, who has had an experience at the front in France, makes the statement that professional football players are not wanted in the trenches because their endurance has been found to be less than one-third of that of the ordinary soldier taken from the desk, the farm, or the shop. This he attributes to the fact that they have been so long tuned to the highest pitch to take part in the game and to the fact that their nerves are so acute that they cannot stand gunfire as can the ordinary man.

For Recreation Resort in France.—A bill has recently been introduced into Congress providing for an appropriation of \$15,000,000 for a recreation center in southern France for American soldiers on leave from the trenches. The bill was introduced by Representative Miller, who has just returned from a visit to the western battle front.

The Control of Venereal Diseases.—The United States Public Health Service has issued a bulletin for the purpose of organizing a nation-wide campaign for the control of venereal diseases. The bulletin states that the control of venereal diseases in connection with the prosecution of the war constitutes one of the most important problems now confronting public-health authorities of the United States. The fact is emphasized that the prevention of venereal infection in the military population is largely dependent on the degree with which these infections are prevented in the civil community. This imposes upon the civil health authorities the duty of forcefully attacking the venereal problem upon the basis of the control of communicable diseases. The Public Health Service in cooperation with the Red Cross and the Medical Department of the Army is establishing venereal clinics in cities in immediate contiguity to the Army cantonments. There is even greater need, it is pointed out, for the beginning of an active antivenereal campaign in those cities which are outside of the military zones, but into which soldiers go in search of recreation. Most important of all is the education of the general public to the end that this disease group will be considered in the same light as other communicable infections. In connection with this announcement, a plan is outlined in accordance with which it is proposed to make this attack.

Camp Doniphan Hospital Inquiry, and Trial of Medical Officers.—The War Department authorizes the statement that following the complaints from the father of one of the recruits that the death of his son was due to neglect and to the deplorable condition of the camp hospital, the War Department has made an investigation of the hospital at Camp Doniphan. As a result of this investigation instructions have been issued by the War Department directing trial by general court-martial of the then commanding officer of the hospital and of the medical officer who examined the soldier in question and sent him to the hospital without

making known the fact he suspected cerebrospinal meningitis. The inquiry shows that, while the conditions were as alleged at the time the complaint was made against the hospital, they were due to the fact that the hospital was called upon to care for a much larger number of soldiers than it was prepared for, and that the conditions complained of no longer exist, and in all probability would never again occur at this hospital.

Deaths in the Service.—Dr. ALEXANDER COOK, first lieutenant, M.R.C., U.S.A., died at Philadelphia on February 21 at the age of 48 years. He was graduated from the Medico-Chirurgical College in the class of 1891. He served for many years as an assistant medical inspector of the Philadelphia Bureau of Health.

Sergt. CHARLES H. PECK, JR., of the Roosevelt Hospital Unit, a son of Dr. Charles Howard Peck, the head of the unit, died of pneumonia in France on Thursday of last week.

Employees of New York Interborough Rapid Transit Give Ambulance.—An ambulance has been purchased with a fund raised by voluntary contributions from the employees of the Interborough Rapid Transit and presented to the United States Government as a tribute to the several hundred Interborough employees serving in the army and navy.

Another Appeal for Red Cross Nurses.—The New York County Chapter of the American Red Cross appeals in the name of Surgeon General Gorgas for 5,000 more army nurses between now and June 1 next. These nurses are needed in the military hospitals both in this country and abroad. A new American Red Cross Hospital has been established at an English port for American soldiers and sailors. The Red Cross has also assumed the support of a hospital in Devon, as well as a hospital for officers at Lancaster Gate, London, which are to be made available in the case of emergency for the care of American troops. It is estimated that approximately 30,000 nurses will be needed in the army hospitals during the present year.

Death Toll of Medical Officers.—A cablegram from London reports that figures just compiled show that since the beginning of the war 505 medical officers serving as combatants have been killed or died of wounds up to the close of the year 1917.

Course in Occupation Therapy for Women.—In the school of Practical Arts of the Teachers' College, Columbia University, a course has been established designed to qualify women to give occupational instruction to crippled, disabled, and shell-shocked soldiers. The student, in order to obtain a diploma, must complete at least seven courses, including: the medical aspects of occupation therapy; the methods of teaching this treatment; observation and practice work with patients in institutions; the elements of psychology; art structure (design), and at least two craft courses. A three-fold equipment is said to be necessary for the teacher of occupation. First, she should understand sick people. In the second place, she must have the psychological background for teaching. Finally, she must be skilled in arts and crafts, the principles of design, and the use of color. The new therapy is to be explained by specialists in nervous and mental diseases.

MEDICAL RECORD.

New York, March 16, 1918.

THE DANGERS OF OPERATION FOR VARICOCELE.

THERE are a great many things taken for granted by the medical profession which are found entirely unwarranted by a strict inquiry into facts, and one of these is the assumption that any intelligent general practitioner can do an operation for varicocele. In fact, who has not heard such a one say: "Well, I'm no surgeon, but at least I hope I can do a varicocele operation." But can he? Yes, the truth is he can, but unfortunately the poor patient often finds himself worse off than he was before. The matter was important enough in civil practice, but the organization of our vast national army has increased its importance a hundredfold. Formerly, a marked varicocele was accepted as an excuse for exemption. Now it is not. The man with a varicocele is taken into the army and required to do his duty as a soldier. If he claims he cannot on account of his varicocele he must have it operated on. Consequently, we are having, and will have, a great many more such operations this year and next than ever before.

Most practitioners on attempting this operation think only of two things: shall they do a high or low operation, the object in both cases being to excise the redundant vessels. The alternative operation, amputation of the scrotum, is hardly ever considered, because the excision operation seems so simple. But it is not as simple as it looks. In fact, there are ten dangers: (1) Superficial infection; (2) deep infection of scrotum; (3) atrophy of testicles; (4) loss of testicles; (5) edema, temporary or permanent; (6) hydrocele; (7) hematoma; (8) tenderness; (9) neuralgia; (10) a chafing or pricking of the scrotum (especially onerous if the patient be a cavalryman). Any one or several of these bad results may occur if the operator be the least careless about asepsis or the tying of blood-vessels or nerves. Besides the actual pain or discomfort following varicocele operation there is also the ever-present danger of becoming a victim of malingering. Neuralgia or neuritic pains may so often actually follow the operation that a soldier's claim that he actually has these symptoms cannot be easily disproved.

On the other hand, there is the alternative operation, amputation of the scrotum, with or without excision of the vessels. This obviates all the drawbacks except infection and possible loss of the testicle. It has many advantages, chief among them being that no nerves or blood-vessels are touched; a soldier, then, who complains of neuralgic pains following such an operation can definitely be branded a malingerer.

Not to enter here upon the technique of scrotum amputation, we will only call attention to a possible contretemps in the operation, namely, severe hemorrhage, difficult to check, and liable to be followed by a hematoma, a fertile field for infection. This is usually due to the fact that after cutting through the skin and subcutaneous tissues, vessels are cut carelessly, and immediately retract away from the field of operation, which they persistently flood with blood thereafter, and a large hematocele will almost surely form. A through-and-through suture of the scrotum before the operation will prevent this, but it leaves a rather awkward stump.

Small varicoceles can be satisfactorily treated without excising the vessels at all. In large ones, excision may be done, but the veins should not be tied, for this leaves an ugly stump. For the benefit of those who hesitate at cutting off part of the scrotum it may be said that it is practically impossible in such a case to remove too much of it. The only logical objection to the scrotum method is the possible return of the varicocele afterward through stretching of the scrotum, and the higher the amputation the less is the likelihood of this. Novocain is better than cocaine, as the edema and after-pains are less marked; occasionally a general anesthetic will be required.

The experience of the army has been that wherever a varicocele causes symptoms operation is indicated; the impression sometimes held that it disappears spontaneously at thirty or thirty-five is not warranted. It may decrease then, and again it may not. Certain it is that it often prevents a man from being a perfect soldier, especially a cavalryman; and the amputation of the scrotum offers the best chance of getting rid of it.

ACIDOSIS IN INFANCY.

AFTER much investigation, the condition known as acidosis, which occurs in diabetes, in connection with pregnancy, after surgical operations, and in infancy, and in which the mortality is so high, is still somewhat of a mystery; its etiology is but little understood and its treatment is unsatisfactory. All the acidoses are symptomatically acute intoxications of rather rapid course. Nearly all of them have such urinary findings as sugar, acetone, and diacetic acid. But although there is so much in common between them, actual similarity of cause has not been determined. In all but the acidosis of infancy the condition has long been recognized. Indeed, acidosis of infancy is of comparatively recent study. It seems that at the bot-

tom of the acidoses of infancy are dietetic errors or disturbances, together with a constitutional intolerance toward or inability to utilize certain food elements. In this respect the carbohydrates and fats are accorded first place. In many infants there is a manifest intolerance for these food elements. In the same individual, however, there may be a different degree of tolerance for more than one food element. At times carbohydrates may be tolerated only in the presence of a low fat percentage; or fats may be assimilated only when the carbohydrates are low. Proteins do not seem to affect the metabolism of either of these two. Yet the assimilation of the proteins may be much affected by the percentage of fats and carbohydrates present in the food. The end products of protein metabolism may then contribute largely to the development of the acidosis. In all probability it is the ingestion of an excess of one or more of these food elements, rather than the mere ingestion of them, that starts the cycle of intolerance. The food injury affects the intermediary metabolic processes in such a way as to diminish subsequent tolerance for the food causing the injury. In a manner it is a true anaphylaxis. This is undoubtedly the nature of the so-called milk-sickness of infants. The intolerance to the milk is rather an intolerance to one of the food elements than to the whole milk. It is significant that this intolerance does not obtain in the case of mother's milk, which again demonstrates the material difference between mother's and cow's milk.

An excess of fat in the infant's food necessitates the use of more of the alkalis of the body for saponification than the body can afford. Much of this oversaponification goes to make up the alkali-soap stools in the fat constipation of infants. If this process proceeds further there is not sufficient alkali left for the neutralization of the inorganic acid end-products of protein metabolism. The excess of acid thus left means, of course, acidosis. On the other hand, the ammonia coefficient of the urine is found increased in these cases because it seems that Nature substitutes this form of alkali for that used for the other purpose. The increase of the ammonia in the urine is a forerunner of acidosis and a cardinal sign of this form of metabolic disturbance. The conditions resulting in acidosis are further aggravated when one of the offending factors is sugar, in that there is an accompanying inability to utilize the whey salts. The intolerance toward carbohydrates, and the consequent inability to assimilate them or the extrinsic withdrawal of them, are the causes of acetonuria, just as in diabetes. The intolerance and withdrawal of the carbohydrates causing the acetonuria are associated with diets rich in carbohydrates and fats, although there is little doubt that the improper utilization of the proteins, whether dependent on excess of carbohydrates or not, shares the guilt. In infants the metabolic disturbances which cause the excretion of the acetone bodies may cause their excretion through the lungs instead of through the

urine, as in adults. This point must be borne in mind in diagnosis.

Usually not much warning is given of the onset of acidosis in infants. The onset is acute. There are diarrhea, vomiting, fever, glycosuria, leucocytosis, coma, and eventually collapse. There is no anemia, because the loss of fluids through the diarrhea leaves the blood somewhat concentrated. Acetone and diacetic acid are almost constantly found in the severer cases. In cyclic vomiting the symptoms and the urinary findings are almost identical, and it is very much of a question whether cyclic vomiting is not merely a transitory form of acidosis. Incidentally, the treatment of both is the same. In an infant with diarrhea and a high ammonia coefficient, even without sugar and acetone, acidosis may be suspected. With hyperpnea the diagnosis is almost certain. Laboratory findings include decrease of the carbon dioxide of the blood and alveolar air, and decreased carbon dioxide combining power of the blood plasma. Fortunately there is an increased tolerance for sodium bicarbonate. When once an acid condition sets in, hypoalkalinization seems to be aggravated by the smallest amount of fat, the intolerance toward this food element becoming greater and greater.

But in spite of the fact that acidosis seems to be of dietetic origin, not much that is hopeful can be said of the general effect of dietetic treatment. It is needless to say that if the basic dietetic error can be discovered correction is the logical course to follow. If the particular dietetic error can be recognized early before there is much intoxication, the withdrawal of the offending element may stave off more profound eventualities. Otherwise the treatment of acidosis settles down to alkalinization. Even if the acidosis is overcome by treatment, there usually ensues such a profound and intractable form of malnutrition as to destroy all that has been gained. In using the sodium bicarbonate to alkalinize, enough of it must be used to render the urine distinctly alkaline and to raise the carbon dioxide content of the blood and alveolar air to normal. Practically the alkalinization of the urine is coincident with the general alkalinization. Neither the administration of this drug by mouth nor the instillation per rectum is as efficacious as the intravenous route. Usually from 75 to 150 c.c. of a 5 per cent. solution is enough for the first dose. A second dose can be given in about eight hours. Even with heroic treatment the mortality of acidosis in infants is still over 85 per cent. Whatever hope there is of reducing this mortality lies in the early recognition of food intolerance and its correction.

NEURASTHENIA AND ITS TREATMENT.

In the *Practitioner* for January, 1918, is published a paper on the management of neurasthenia, psychasthenia, shell shock, and allied conditions, by Dr. Frederick C. Forster, in which the author points out that while neurasthenia may be of many differ-

ent types the sufferers nearly always have in common certain symptoms, the most prominent being depression, lassitude, often combined with a curious restlessness, insomnia, loss of power of concentration, failure of memory, abnormal sensations in different organs, tremblings, dragging pains, palpitation, loss of appetite, and loss of vitality. This is a true word picture of the symptoms of a neurasthenic, not that they are all combined in one sufferer, but they are the conspicuous symptoms that are apt to occur. Worrying over his complaints and imaginary complaints is a characteristic feature of the sufferer from neurasthenia. He attaches undue importance to all his disagreeable sensations, and is especially anxious with regard to the tachycardia, which is a frequent accompaniment of the condition, imagining it to be a sure indication of a serious heart lesion.

The cure of a neurasthenic involves infinite patience and tact on the part of the medical attendant. First of all, in treating a case it is incumbent on the medical man to make a correct diagnosis, and definite disease of any organ must be eliminated before it can be said to be a true neurasthenia. Assurance must be had that the condition is not owing to toxemia, influenzal or gastrointestinal, for the depression accompanying or following a toxemia of this description cannot be labeled or treated as a neurasthenia. Forster holds that the keynote of the management, a term he uses purposely in preference to treatment, is to induce "self-forgetfulness," to do away with the inertia, to improve the morale by encouraging a feeling of independence, and to adjust the patient's life so that petty troubles and annoyances take their subordinate position, whether this is achieved by some wholesome and pleasant occupation, by drugs, or by some of the many other methods which may be employed. The Weir-Mitchell rest case is recommended, and it is pointed out that, apart from the dieting, the chief essential is to procure sleep for the patient. As for drugs, chloralamide is to be preferred to either paraldehyde or the bromides, and for the general excitation monobromated camphor with conium is useful. It is not advisable, however, to prolong the Weir-Mitchell treatment after the acute stage has passed off.

It really is an interest in life that such people need. The author is not an advocate of drug treatment. Regarding change of air, scene, and climate, which really means change of environment, the suggestion is put forth that although it is not always possible to change the physical environment, yet much, very much, can be achieved by altering the mental or psychical environment, and the power of creating a special mental environment is helpful in turning what is repulsive into what attracts. In short, in neurasthenia it is the person, rather than the disease, that demands treatment. Finally, a return to work or occupation is likely to be of greater benefit by far than rest cures; that is to say, in a large proportion of cases.

SUBSTITUTE FOR ABSINTHE.

THE abolition of absinthe selling in France as a war measure has evidently led to the sale of imitations and substitutes. An article by Dage in *Le Caducée* for December 15 quotes from *Le Matin* to the effect that of 31 individuals prosecuted in the arrondissement of Bar-le-Duc for the sale of absinthe substitutes all received light fines with the added penalty of confiscation of the liqueurs. This brings up the subject of absinthe succedanea, which long ago claimed attention in Switzerland. As is well known the French law, which went into effect on March 16, 1915, was based on the Swiss law of 1910. Yet the Swiss courts once refused to convict venders of substitutes by reason of their plea that the latter were free from *thuyone*, the substance alleged to cause the ill effects of absinthe. It has since been decided that the thuyone theory is based on false premises, and the immunity of the substitutes on this ground no longer holds good. When the sale of absinthe was legal and falsification was practised, "similar" substances meant any substance, irrespective of name or analysis, which was sold with the implication that it fulfilled the rôle of absinthe. As a consequence much confusion was rife. Any substance which contained thuyone could be regarded as belonging to the absinthes. On the other hand, "oxygenated absinthe" was sold with the implication that it had been "dethuyonized." The "thuyone" legend was exploded once for all in 1912 when the Agricultural Department reported after an investigation that few of the plants employed in the manufacture of absinthe contained thuyone. As long as this heresy existed essences of anise, fennel, etc., could be freely sold because the obnoxious substance could not find its way into these simple products. As long ago as 1889 it was shown that the toxic substances which did or might enter into the composition of absinthe were of two types: a convulsive type was represented by absinthe proper, hyssop, fennel, etc.; while a stupefying type comprised anise, mint, coriander, angelica, organum, balm-mint, etc. Not one of these substances contains thuyone. The question "What is absinthe?" is doubtless as difficult to answer as the British query, "What is whiskey?"

HISTORY OF MEDICAL JOURNALISM IN CUBA.

IN 1840 there appeared in Cuba the pioneer medical publication, known as the *Repertorio Médico Habanero*, coincident with a movement for scholastic reform, which included secularization of the university and utilization of clinical material. During the period 1840-1863 half a score of other journalistic enterprises were begun, all of which were apparently shortlived. Three years after the foundation of the Academy of Medical, Physical, and Natural Sciences in 1861, the annals of this body began to appear and have been issued regularly so that at present they number 54 volumes. The *Crónica Médico-Quirúrgica*, which began in 1875, has continued to the present day and is the dean of Cuban medical journals. Its founder and editor was Dr. Santos Fernandez. For many years the *Cronica* and the *Anales* mentioned above were the only successful examples of medical journalism on the island, among many ventures; al-

though the *Archivos de la Policlínica*, which ran from 1892 to 1908, must be ranked as at least a partial success. The third permanent periodical, the *Revista de Medicina y Cirugía de la Habana* was begun in 1896. The fourth "live" journal founded in 1902, is the *Revista Médica Cubana*. A number of other current journals exist, most of which are of recent origin. *La Prensa Médica*, however, has published 18 volumes since 1910 and the *Archivos de Medicina Interna* is in its sixth year. Not a few "dead" journals went through numerous volumes and doubtless represent a material contribution to medical literature. One (*Archivos de la Policlínica*) has already received mention and there are numerous others, some of which deal with collateral subjects, as dentistry and anthropology.

ARCHAIC POSTAL LEGISLATION.

CONGRESS has turned back the hands of the clock to the year of Our Lord 1863, by reestablishing the "zone" system of postage for periodicals, which Lincoln abolished in that year. We reproduce on page 486 an article by the novelist, Rex Beach, distributed at the instance of the Publishers' Advisory Board, which describes very clearly the nature and probable consequence of this law. We urge our readers, and particularly those who live at a distance from New York, to write or telegraph to their Senators and Representatives in Congress, and express plainly their disapproval of the law, and their desire for its prompt repeal.

News of the Week.

New York Starts Campaign to Save Babies.—The conference board of the Council of Women's Organizations held a meeting on March 3, at which it was decided to begin active cooperation with the Federal plan for the reduction of infant mortality. The Council of Women's Organizations includes 350 women's clubs and associations throughout New York City and was organized for the purpose of placing the activities of these organizations on a war basis. One of the subjects discussed at the meeting was the prohibitive price of milk. No time is to be lost in preparing for summer by undertaking a city-wide propaganda to anticipate the trouble and high price it will bring. Definite plans will be announced at a meeting to be held later this month.

Physical Training in Schools.—Dr. Eugene Lyman Fisk has issued a protest against the various amendments pending in the Legislature which would weaken the present system of compulsory physical training in the rural schools of New York State. He cites authorities showing that the country children are as much in need of this training as those of the city and that the health of the country child is from 5 to 20 per cent. more defective than that of the city child. He quotes the results of the physical examination of drafted men to show that the whole health situation both in the city and the country is alarming and constitutes an unanswerable argument for the enforcement of every conceivable kind of health measure.

Smallpox in New York State.—According to a report just issued by the New York State Health Department there have been a number of out-

breaks of smallpox during the past year in various parts of the State and the disease has also been prevalent in other States as well. Early in November the disease made its appearance at Rome and from there it spread to Utica, where there were 47 cases within two months, and to Frankfort and Herkimer counties, there being 78 cases in Frankfort County. Altogether over 250 cases of smallpox have been reported to the Health Department within the past few months. A study of the history of these cases in reference to previous vaccination shows that of 348 cases reported in 1917 only two had been vaccinated within seven years and of 94 cases thus far reported in 1918 only two had been vaccinated within the seven-year period. The State Health Department points out that these figures speak for themselves regarding the value of the protection conferred by vaccination. In commenting on this report of the State Health Department, the Health Department of New York City calls attention to the fact that four of the six cases of smallpox that have been reported in New York City have occurred among negroes, and that the importance of vaccination against smallpox should be impressed upon this class of the population.

Sanitation in Extracantonment Zones.—In the February *Bulletin* of the State Department of Health, Frank Overton, sanitary supervisor of the State Department of Health, gives his experience with the problems of sanitation that arise in the vicinity of the large army and navy stations on Long Island. He points out that a great aid in enforcing sanitation was the threatened application by the army and naval authorities of the law giving them full power to exclude uniformed men from unsanitary places in prescribed zones around the camps. Conditions have been aggravated by the uncertainty of military plans and by the unscrupulousness of camp followers, who consider only opportunities for immediate gain. An armed sentinel in front of an establishment, it was found, furnished an object lesson that was heeded by the most grasping proprietor. One or two such demonstrations had more effect than a dozen civil lawsuits, with their delays and subsequent ill feeling. Immediate publicity given an unsanitary condition is based upon the same principle and has the same effect as placarding the house of a patient suffering from a communicable disease. There are good reasons why some method of publicity should be applied as a routine measure by all boards of health to every unsanitary place of importance. After the camps have been established on a settled basis the sanitary supervisor has brought to the attention of local boards of health the matter of sanitation of places used for the sale of foods and drinks. Simple regulations were adopted governing such essential matters as cleanliness, covering foods, washing dishes, garbage disposal, and the personal hygiene and health of employees. Health officers were instructed to inspect all places selling foods and drinks, and to issue certificates to those found to be sanitary. The military authorities announced publicly that they would accept the certificates of inspection and exclude their men from unsanitary places. This cooperation of the civil and military authorities has been effective in securing sanitation in practically every instance. This procedure the writer finds has benefited the civil population

quite as much as it has the soldiers. It is suggested that similar inspections and certificates would be found valuable in other extracantonment zones and that they might be made applicable in every health district, particularly at fairs, circuses, and other temporary places of assembly. One of the grave problems that has presented itself is the disposal of the numerous horses which die among the 10,000 animals at Camp Upton remount station. Although incineration is wasteful and expensive it seems to offer the only solution of the problem at present. The control of venereal diseases in the extracantonment zones of Long Island has been receiving the earnest attention of the health authorities. Open prostitution has been comparatively rare. The problem of controlling concealed sources of infection has been met by three measures: (1) reporting known sources of infection in the soldiers to the health authorities; (2) controlling carriers of infection when they are found; (3) preventive work by the Women's Committee to protect young girls promises to have a most beneficial and widespread result.

Anthrax Victim Cured.—A longshoresman who contracted anthrax while handling hides from Argentina was taken to Bellevue Hospital on February 14 and discharged cured on March 8. The cure was effected by the removal of the infected part on the man's neck and an injection of Eichhorn's serum.

Arrest for Smuggling Neosalvarsan.—A Dutch diplomat has been arrested and held in \$2,500 bail for having smuggled \$40,000 worth of neosalvarsan into this country. He claims that the drug was for the use of the Australian Red Cross. The duty on neosalvarsan is 25 per cent.

Dr. George A. Knowles has been appointed a trustee of the Pennsylvania State Hospital for the Insane at Norristown.

Dr. Wesley Grove Vincent of this city has been appointed provisional assistant visiting physician to the Harlem Hospital for 1918.

The American Posture League.—At the annual meeting of this association, which occurred March 9, closing with a dinner for the honorary boards at the Aldine Club, the following officers were elected: *President*, Miss Jessie H. Bancroft; *Vice-President*, Capt. Frederick R. Green; *Secretary*, Dr. Henry Ling Taylor; *Treasurer*, Dr. Percy W. Roberts. The reports for the year showed a great activity in relation to war conditions, and a large demand on the resources of the league, as a national health organization, indicating a quickened public conscience on the subject of health since the physical examination for the army disclosed such a low standard of health throughout the country. The technical committees of the league reported completed work for the year on factory and school seats, shoes, and other articles of clothing for men, women, and children, beside a large educational service.

Study of Childbearing Mortality.—At a meeting of the New York Obstetrical Society, on February 12, 1918, the following resolution was unanimously carried:

Whereas, The advisability of an intensive study of the mortality associated with childbearing would prove of undoubted advantage to the medical profession and the public; and

Whereas, Such a study, based on statistics derived

from hospitals of this borough, is about to be undertaken, with the assistance of the Public Health Committee of the New York Academy of Medicine, therefore, be it

Resolved, That the investigation of the mortality associated with childbearing, instituted by the Public Health Committee of the New York Academy of Medicine, as presented at the meeting of February 12, 1918, receive the hearty cooperation and indorsement of the New York Obstetrical Society.

Conference of Industrial Physicians and Surgeons.—The Department of Labor and Industry of Pennsylvania will hold its sixth conference of Industrial Physicians and Surgeons in the hall of the House of Representatives at Harrisburg on April 9, 1918. An invitation to attend and participate in this conference is extended to all medical men interested. At the morning session there will be brought up the subject of industrial health hazards arising out of the war emergency. The afternoon session will be devoted to the subject of workmen's compensation. The question of hernia in its relation to the compensation law and the possibility of amendments to the present Pennsylvania workmen's compensation law will be discussed. Copies of the program may be obtained on request from Dr. Francis D. Patterson, chief, Division of Industrial Hygiene and Engineering, Third and North Streets, Harrisburg, Pa.

Obituary Notes.—Dr. JOHN GEORGE BLAKE, a graduate of the Harvard Medical School in 1861, died at his home in Boston, on March 4, at the age of 81 years.

Dr. WILLIAM SCOTT KENDRICK of Atlanta, Ga., died at his home in that city, on February 22, aged 75 years. He was a graduate of the Atlanta Medical College in 1874, and for some years professor of physical diagnosis and clinical medicine in that institution. In 1915 he was made senior professor of medicine at Emory University. Dr. Kendrick was for many years the medical director of the Southern States Life Insurance Company.

Dr. JAMES H. WOOD, a graduate of Vanderbilt University, medical department, in 1882, died at his home in Attalla, Ala., on February 28, aged 61 years.

Dr. JOHN HENRY MULLEN, a graduate of the Harvard Medical School in 1900, died of heart disease at his home in Lynn, Mass., on February 21, aged 41 years.

Dr. BENJAMIN RALPH SWAN, a graduate of the College of Physicians and Surgeons, New York, in 1868, and for many years the medical referee of the Mutual Life Insurance Company of New York, died at his home in San Francisco, about February 20, at the age of 81 years.

Dr. ALFRED M. TOWNSEND, a graduate of the Ensworth Medical College, St. Joseph, Mo., in 1893, died following a long illness at his home in Quitman, Mo., on February 26. He was a former resident of St. Joseph, Mo.

Dr. JOHN M. BERRY, a graduate of the Washington University, medical department, St. Louis, Mo., in 1878, died at his home in Webster Grove, Mo., aged 63 years.

Dr. HORACE LADD died at Philadelphia on February 24 at the age of 92 years. He was graduated from Jefferson Medical College in the class of 1848.

Dr. ALPHEUS A. CORBIN of Pueblo, a graduate of the Bennett Medical College, Chicago, in 1872, died of pneumonia at his home in that city, at the age of 76 years.

Dr. FRANK MARSHALL READE, a graduate of the Medical College of Virginia in 1899, died at his home in Richmond, Va., on February 26, aged 55 years. He was for many years a member of the finance committee of the City Council of Richmond.

Dr. JESS C. ELDRIDGE, a Civil War veteran and for many years a practising physician of Chattanooga, Tenn., died at his home in that city, aged 73 years.

Dr. JOSEPH O. GREENLAW, formerly of Franklin, La., died of tuberculosis in Artesia, N. M., on February 27, aged 44 years.

DRUG ADDICTION.

RECOMMENDATIONS OF THE NEW YORK PSYCHIATRIC SOCIETY AND THE PUBLIC HEALTH COMMITTEE OF THE NEW YORK ACADEMY OF MEDICINE.

The fact that a new element is entering into the causation of drug addiction in recent years, and that it has been a matter of State investigation and much public agitation makes it very desirable that the medical profession take some definite position and action in the matter. The points under investigation and discussion are the causes and prevalence of drug addiction, the methods of treatment for relief and treatment for cure, and the methods of legislation for the dispensing and control of drugs. With regard to these points we have reached certain conclusions and made certain recommendations, as follows:

1. We recommend that the Federal Government take such measures as are feasible to abolish the manufacture of heroin altogether.

2. We recommend that the Federal Government be urged to adopt such legislative measures as will control and regulate the sale and distribution of opium and its derivatives and of cocaine, from the time of its manufacture to the time of its final distribution; also, that it take measures with regard to preventing the importation of these drugs except under proper conditions.

3. We recommend that the Federal Government do not, at present, extend its jurisdiction to the control of all habit forming drugs, but that the control of special drugs be taken up as occasion seems to demand.

Experience in New York City and the East shows that there is no great prevalence of drug habit aside from that of opium and its derivatives.

4. We recommend that a thorough study be made of the extent and causes of drug addiction; such studies, for example, as will give information as to the age, sex, occupation and environment, and the mental and physical condition of victims of the drug habit, and as to how their habit was formed.

With regard to the cause and frequency of the habit, we can make only provisional statements. So far as our knowledge goes, the drug habits formed as the result of long and painful sickness, as the result of painful surgical operations, and as the result of mental causes like sorrow, depression and apprehensive states, constitute at present as in the past, a negligible proportion of the total.

The habit has largely been formed in recent years by association and imitation by boys and young men and women who are often quite ignorant of the dangers of the habit. Examination of a long series of addicts at Bellevue Hospital shows that about four per cent. formed the habit through the advice and prescription of unscrupulous physicians who utilize what is known as the reduction treatment as a cover for their reprehensible practice.

So far as the number of addicts is concerned, we find some estimates by Martin T. Wilbert, U. S. Public Health Service Bulletin No. 321, to the effect that there are not over 175,000 addicts in the country. Estimates made by Dr. Kirby, based on available sources of information, show that there would be perhaps 7,000 to

8,000 in Greater New York. These estimates of Dr. Kirby's are based on the statistics of Bellevue, Metropolitan, and Kings County Hospitals, and on the reports from the hospitals of the Department of Correction.

There is an impression among some that the drug-addiction is *enormously prevalent* and is *rapidly growing* and becoming a serious menace to society. It is extremely important to find out the truth as to this. The Public Health Service states that about four million grains less of opium were imported into the United States in 1915 than in 1914, and about five million less than in 1913, but this may be due to the war.

5. We recommend that there be psychological and psychiatric tests made of a long and definite series of addicts.

No serious and comprehensive study of these problems has yet been made so far as we can find. Such information upon the subject of drug addiction can be gathered best through the agency of paid experts who will visit hospitals, courts, prisons, and reformatories, and who will interview such physicians and judges as are experienced in these matters.

6. We recognize that the Surgeon Generals of the Army and Navy have taken a special interest in the subject of drug addiction. We recommend that if it has not already been done, some special study be made of the condition of drug addiction in the Army and Navy and special care be taken to discover the existence of addiction in recruits. We understand that the Surgeon Generals of the Army and Navy are already making special provision for the care and treatment of drug addicts.

7. We recommend that an attempt be made to plan some means of education of young men and women as to the dangers of habit forming drugs. We advise against the use of "movies" or of any sensational methods.

9. We recommend that more attention and publicity be given to the facts which appear to have been established by long experience at Bellevue Hospital and elsewhere. The experience at Bellevue Hospital, after testing with many cures, shows that the drug can be withdrawn from the victim without any special cure being used and it seems to be established that withdrawal can almost always be done safely and surely under ordinary hospital conditions where there is competent nursing and control.

10. We recommend very strongly that treatment for drug addiction should be given only to patients in properly organized hospitals or under institutional conditions, for it is the experience and conviction of all that drug addiction can be relieved and cured best in this way.

11. We recommend that the State do not at present undertake the cure of drug addiction, because the treatment and the subsequent plan of co-operative contact required for success is long, expensive and difficult unless carried out in the local community itself, and the State is not now equipped to undertake such work.

We recommend that in preference to this, at the present time, the State do what it can to prevent the development of new cases and encourage provision for the relief of present sufferers.

12. We recommend, for the relief of present sufferers and perhaps at times for radical treatment, the use of psychopathic hospitals or pavilions and that special provisions be furnished in general hospitals throughout the State to care, under proper control, for those who ask for a withdrawal treatment. This, we think, is what is due the patient who by law is deprived of the drug.

13. Finally, pending action by the Federal Government for the better control of habit forming drugs, we recommend that the State of New York pass some law which will control the matter of drug addiction and the use of drugs by physicians in a better, more efficient and more practical way than does the present law. We leave the definite solution of this as a separate problem in technical legislation.

The plan now under consideration is to simplify the present law and make it mainly supplementary to the existing Federal law, and to issue licenses to those physicians who treat drug addicts.

New York, Feb. 25, 1918.

Correspondence.

THE PROBLEM OF MENTAL DISORDERS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The article of Dr. Walter B. James in the *MEDICAL RECORD* of March 2 merits the earnest attention of the medical profession, inasmuch as, differing from most members of committees, he has made personal investigation of the subject and he writes from the standpoint of the clinician. He presents an optimistic attitude, rarely if ever displayed by the specialists in psychiatry. The latter have, as he well says, surrounded their own special field with such obscurity as to discourage the family doctor.

While I believe that the neurologist is more frequently in clinical contact with mental diseases and is therefore more competent than the general practitioner for their management, I do regard psychiatry as a specialty distinct from neurology, just as, for example, gynecology is distinct from general surgery. The gynecologist usually has been an intern or clinical assistant in institutions devoted to this specialty and is therefore more competent in their management than is the general surgeon. The family physician certainly acts upon this idea in consultations. Within my own acquaintance there are few neurologists who have served as clinical assistants in institutions for mental diseases, and yet many family physicians entrust the care of these cases to our friends the neurologists, regardless of previous clinical experience in this special department. Personally I have not adopted this course.

I agree with Dr. James that "there are many points of resemblance between problems presented by insanity and tuberculosis" and that in the latter disease the former may also be inhibited by methods of prevention. I would add, however, that just as in tuberculosis the treatment of the earlier stages has been of enormous value in preventing the development and by arresting the diseases in its diffusion among the people, so do I believe that similar results may be attained in insanity. And right here is a point which, from the clinical standpoint, I would emphasize. Quite contrary to my observation in tuberculosis, the application of water in the treatment of the insane has been advocated by nearly every author on the subject, and there is no modern institution which regards itself as up-to-date without a hydrotherapeutic plant, and yet it is unfortunately rarely applied in the precise and methodical manner which is in vogue in medicinal dietetic, or other treatment, from which alone favorable results may be expected. That the latter is not the case has so frequently come under my observation that, loath as I am to take this critical attitude, it is my duty to do so.

There are very few institutions in this country in which a physician or nurse trained in the technique of hydrotherapy under competent tutelage is active. A few examples might suffice:

In one State hospital, admitting nearly two thousand cases yearly, a hydrotherapeutic plant was instituted about twelve years ago which I found two years ago to be little used because the temperature and pressure were unreliable. This was due

to the fact that the advice of the manufacturer of the apparatus to connect the latter with a separate supply of water from the main, as is my rule, was not regarded as necessary by the engineer of the institution. Thus hundreds of patients have failed to receive the benefit of this treatment which the State had provided. If a physician or attendant trained in hydrotherapy had been in charge he would have discovered this defect. Despite the fact that I suggested a simple mode of remedying this defect it has not yet, as far as I know, been accomplished.

In another institution, which is regarded as the most modern and scientific in this country, the director of the hydrotherapeutic plant asked me where he could procure an apparatus in which patients could obtain a nebulous spray, in lieu of the continuous (hammock) bath, believing that the former would be more effective than the latter. It did not seem to occur to this presumably expert hydrotherapeutist that the nebulizing of water would cool it by evaporation and thus the favorable effect of continuous warm moisture would be precluded.

In a recently constructed building for three hundred patients connected with a State institution housing several thousand insane, the hydrotherapeutic installment involves, among other defects, the passing of the nude patient, emerging from the hot-cabinet, across the end of a long, wide hall, before entering the douche room. Funds to remedy this and other defects which would neutralize the good effect of the treatment had been refused by the State Commission.

Other flagrant evidence of the unfamiliarity of some of our most eminent psychiatrists with the technique and physiological action of water in the management of the insane is omitted here, although it is even more convincing than those above cited, because public policy demands its suppression. Anyone legitimately interested in this matter may by personal interview obtain all the data at my disposal, which go to show that the optimism of Dr. James would be greatly justified if psychiatric institutions would use water in the treatment of the early stages of insanity, as it is used in some public institutions for the treatment of pulmonary tuberculosis. (See Reports of Hospitals of Department of Charities, New York City, for April, 1917.)

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE SUPPLY OF MEDICAL OFFICERS TO THE BRITISH FORCES—THE MEDICAL SERVICE OF THE AIR-BOARD—THE MILK SUPPLY FOR CHILDREN AND MOTHERS.

LONDON, Feb. 23, 1918.

THE British Army has been supplied for practical purposes throughout the war with medical men of every pattern and standard, and almost of every age, by the voluntary efforts of the medical profession, acting through the Central Medical War Committee. The establishment of the Royal Army Medical Corps was quite a small one, graded to match a quite small standing army, and almost at the outset of the war, when the size of the struggle could be

faintly foreshadowed, it was clear that one of the great difficulties to be faced was the supply of medical men for an army that was to be multiplied at least by ten. Some said with horror that at least 5,000 civilian doctors would be required with the army; some, in calmer mood, because they saw more clearly, put the lowest figure of the requisition at 8,000; and, in the event, with wonderful equanimity, the civilian doctors agreed that every one of them who could be spared must accept a commission. This number already bulks nearly double of any estimate. To decide who could be spared, the Central Medical War Committee came into being, and was recognized by the Government as a statutory body to which medical men might repair for exemption from military service, when age and fitness made them liable to the military demands of increasingly severe conscription. To their committee the War Office also decided to look for their supply of military medical officers. For over two years now the Central Medical War Committee, with the organization of the British Medical Association at their disposal, have discharged their double and difficult duties, and they have not received from the public the general recognition of their services which has been well merited. For the work has been invidious, delicate, and arduous. The medical registers of England, Wales, and Scotland (where an affiliated Scottish bureau has discharged similar functions) have been classified, the man-power of the medical profession in each center of population has been tabulated, and the medical men of military age, who have been called up for service, have been sifted with a double eye to the needs of the War Office and the needs of the civilian population. In this way, and with the greatest difficulty sometimes, the military *cadre* has been kept complete, and the ordinary preventive and therapeutic services of the country have been preserved from complete dislocation even when depleted to an unthinkable extent. But lately the demands upon the committee for the delivery of military officers to the War Office, on the one hand, and for the retention of practitioners in their civilian occupations, on the other, have become very acute, and at the close of February the committee was compelled to send a formal request to the Government, urging that the duties of medical officers serving with the forces should undergo revision, in order to obviate further calls upon the civilian medical practitioners. The request is a perfectly reasonable one. The committee have reduced the number of civilian medical practitioners almost to the danger point, and have the right of good work done in asking that before being called upon to pursue their policy further they should be assured that an economical use is being made by the army of the vast number of military medical officers already passed forward for commissions. The war has been in progress three years and a half, and in many directions and spheres its conduct has taken on a routine shape which allows of fairly accurate forecasting. The War Office is asked, though not in so many words, to ascertain whether too many medical men are not being employed in certain positions under the existing scheme, and, this being ascertained to be the case, whether future needs cannot be met by a more economical use of the officers already in their serv-

ice. And this is a most reasonable representation on the part of the Central Medical War Committee, which has done splendid work.

A powerful plea has been published for the immediate constitution of a special medical service for the recruiting and treatment of flying men. It is obvious that the flying man should be the fittest of the fit, and that he must be kept so. The ordinary scrutiny given by a medical board to a candidate for a commission, however careful, would often not be sufficient in the circumstances. The special examinations that should be conducted call for the intervention on many occasions of medical knowledge of high and particular quality, and would be expected only from members of a selected service. Similarly, the care of flying men when in discharge of their dangerous duties is a matter requiring not only general medical knowledge of a thorough sort, but real familiarity with the outlying paths of, for example, ophthalmology, otology, and psychology. It is easy to see that a service of this high scientific standard is so desirable that it ought certainly to be established if we consider what would be expected from it. It would be asked from its work among the flying men to deduce the rules for its own guidance in recruiting those men. Accidents occur sporadically, but assuredly have often a common cause; accidents, therefore, should be grouped in classes and the utmost acumen brought to bear upon the problems of their common factors. Armed in this way the medical boards could look for defaults in physique and temperament which at present pass unnoticed, and the candidates, while not being rejected could be given training on the ground and at the aerodrome before being admitted to more perilous work. The number of accidents would go down, not only because of the intelligent sifting, but because the increased safety, becoming known to the young recruits, would protect them from psychological strain. Much of this was implied, and some was said, in the House of Commons last week by Sir Watson Cheyne, late president of the Royal College of Surgeons of England, and now a surgeon general in the Navy and member of Parliament for the University of Edinburgh, when he stated that a scheme for the air medical service had been passed for adoption; but his words were far from constituting unreserved praise for the scheme, and it is an open secret that in several official places the medical claims for a specially constituted service were considered unjustifiable. No medical man can doubt in such a controversy on which side the right lies, and it is to be hoped that the scheme will be found sufficiently elastic to allow of expansion in the direction necessary for the greater safety of the most gallant wing of every army competing in the world war.

The question of milk for nursing mothers and children is necessarily occupying the attention of medical practitioners all over the country, but their immediate anxiety here this week has been met by a wise regulation. All nursing and expectant mothers are now entitled to the amount of milk certified for by medical men. Every child under 18 months of age is entitled by the same administrative order to 1½ pints of milk daily, and between 18 months and 5 years to one pint daily. At various centers established for child welfare priority

certificates for the milk will be granted, as well as by medical officers of health for the districts. The price will be made to fit the means of the applicants, the local rates and the Government sharing the cost of any deficiency.

Progress of Medical Science.

2. Lithiasis with Bilateral Renal Involvement. W. F. Braasch.
3. Fracture of the Neck of the Femur; Report of Three Cases. Charles E. Ayers.

2. **Lithiasis with Bilateral Renal Involvement.**—W. F. Braasch bases this article upon a study of 62 cases of bilateral nephrolithiasis occurring at the Mayo Clinic from January 1, 1910, to October 1, 1917. In the same period there were 504 cases of unilateral nephrolithiasis—a percentage of 12.3 of bilateral trouble. Bilateral as well as unilateral lithiasis occurred twice as often in the male as in the other sex. Pain in bilateral nephrolithiasis was unilateral in 64 per cent. and absent in 8 per cent. of the cases. Bilateral stones were found most frequently in the pelves and calices. Combined renal functional tests were of practical value only when normal or extremely low. To ascertain the comparative degree of function in the two kidneys, the functional test was of value only when it was zero or a trace, normal or excessive. The functional test, x-ray examination and cystoscopic inspection may be insufficient in determining the degree of healthy renal tissue remaining, and exploration only can determine this. Indications for operation: (a) The kidney with acute complications should be operated on first; (b) without acute complications the kidney with the better function should be operated on first; (c) occasionally simultaneous bilateral operation is advisable. Patients may be inoperable because of renal insufficiency, secondary infection, kidney destruction, or constitutional complications. Patients with large bilateral stones causing no symptoms or complications are better off without operation. The operative mortality in this series was zero; the total number of deaths after operation 10; these patients died less than a year following operation. The operative mortality with calcareous pyonephrosis is much greater than with other forms of bilateral lithiasis. The recurrences in cases of bilateral nephrolithiasis was 20 per cent.; in unilateral lithiasis, as previously reported, it was 10 per cent. When there is stone in one kidney the most common forms of disease in the opposite kidney are: Pyelonephritis, pyonephrosis, and hydronephrosis. With unilateral lithiasis the opposite kidney may be so badly diseased that a preliminary operation may be advisable on that kidney. Stone secondary to pyelonephritis, when removed, prevents further renal destruction but is not of curative value. When the nephritic element predominates, removal of the stone is not of much therapeutic value. A single kidney has a great degree of tolerance for repeated operation for stone. In a single kidney the phenolsulphonephthalein output usually remains high in spite of the presence of an uncomplicated stone which is probably due to compensatory hypertrophy. Fused or horseshoe kidneys permit of repeated operation for lithiasis which may, if necessary, include heminephrectomy.

4. The Surgical Aspects of Gastric Hemorrhage.—

George Woolsey points out that the cause of gastric hemorrhage may be in the stomach or outside. Hemorrhage from gastric ulcer is not so frequent as is often supposed, and hemorrhage, *per se*, is of little value in the diagnosis of ulcer. The correct diagnosis of the cause of the hemorrhage is made in less than half the cases. The cases of gastric hemorrhage curable by surgical operation are those due to chronic ulcer and carcinoma and to diseased conditions of the appendix, gall-bladder, and spleen. Operation should not be performed during profuse hemorrhage. Such cases should be treated medically and operated on when the patient has sufficiently recovered, if chronic ulcer is suspected. Care should be taken in cases of repeated hemorrhage to operate before the patient becomes profoundly anemic. Transfusion may save life, or may simply check the hemorrhage and make the patient an operable risk. Gastroenterostomy is the simplest and safest operation, but alone or even with pyloric exclusion is not an absolutely certain cure. Under favorable conditions excision or resection should be done, but care should be taken not to attempt too much. If there is no ulcer the appendix, gall-bladder, and spleen should be explored, and removed if pathological.

3. **Trichinosis: A Report of Three Cases Simulating Meningitis, with the Findings of Trichina Larvæ in Spinal Fluid.**—Jacob Mayer gives the histories of three cases of trichinosis, in two of which definite clinical symptoms of meningitis were produced by trichinæ in the spinal fluid. In addition to the trichinæ the spinal fluid showed an increase in lymphocytes, from 240 to 40 per cubic millimeter, reduced the Haines solution, and gave a positive Ross-Jones test. Meyer calls attention to the necessity of differentiating early cases of trichinosis with meningeal irritation from cases of poliomyelitis. The diagnosis of trichinosis may be established by the occurrences of edema, the presence of an eosinophilia in the blood picture, and the isolation of the trichinæ from the spinal fluid or muscle. Urticaria developed in one case, the differential count being 12 per cent. when the urticaria first appeared and 10 per cent. twenty-four hours later.

10. **The Dust Hazard in Certain Industries.**—T. Grier Miller and Henry Field Smyth point out that although dust as a health hazard in industry has attracted considerable attention, few exact studies of its nature and quantitative features have been published. It is necessary that definite knowledge be gained as to how dust affects health and the manner in which the resultant pathologic conditions are brought about, and it is of prime importance to appreciate certain things about dust itself. A study of dust samples taken directly from the air, at the respiration level, of sixty-five departments of twenty-two plants, representing five industries dealing with inorganic and four with organic materials, has led to the following conclusions: (1) For a complete understanding of the problem of dust in industry, there must be considered not only its weight, but also the number of the particles, their

nature, whether organic or inorganic, and their percentage distribution according to size. (2) The order of the industries studied in regard to dustiness, as determined by weight, was (a) Portland cement, (b) plush, carpet and blanket, (c) flint grinding, (d) steel grinding, (e) asbestos, (f) felt hat, (g) pottery, (h) cigar, and (i) silk. (3) The order as determined by the count of particles was the same except that (a) the asbestos, (b) the plush, carpet and blanket, and (c) the felt hat industries were given lower positions. This was largely due to the presence of fibers in these dusts, which it was impossible to include in our counts. (4) The so-called organic dusts were invariably composed of both organic and inorganic materials, and the latter ingredient may account for the harmful influences which have been attributed to certain of these dusts. (5) The organic dusts averaged less than the inorganic dusts, both in weight and in count of particles. (6) The percentage distribution of the different sized particles was curiously similar in all the samples, and it may be assumed that approximately half of all dust particles that are countable by the method here employed are about 1 micron in greatest diameter, the others ranging up to about 40 microns. (7) Dust removal at the point of production not only greatly decreases air dustiness, but particularly removes the smaller particles. (8) The substitution of wet processes for dry ones effectively lessens air dustiness. (9) Air dustiness varies inversely with relative atmospheric humidity, as does also the percentage of the larger dust particles. The dust samples were collected by means of the Palmer apparatus, and the determinations made by the methods of Palmer, Coleman, and Ward, as modified by Smyth.

1. Further Observations on Acidemia in Gas Gangrene, and on the Conditions Which Favor the Growth of Its Infective Agent in the Blood Fluids.—Almroth E. Wright and Alexander Fleming show by means of experiment that the growth of gas gangrene microbes is favored by the reduction of the alkalinity of the blood and they suggest that wherever, as in the dead body and the muscles, we come upon conditions which specially favor the growth of these microbes, there acidosis is likely to be the operative factor. They further demonstrate that the gangrene bacilli, by elaborating acid, can make for themselves favorable conditions at the site of infection and in the blood generally. Wright and Fleming have been able to prove experimentally that the gas gangrene bacilli of subordinate rank—i.e. *Vibrion septique*, *Bacillus adematians*, *Bacillus fallax*, and *Bacillus acrofatidus* of Weinberg, all of which are occasionally found in gas gangrene—behave in the same way as the *Bacillus* of Welch in that they grow with difficulty in normal serum but grow more and more freely as the alkalinity is blunted off. With the possible exception of *Bacillus fallax* they one and all when they grow freely make the serum acid. The post mortem appearances of Welch's bacillus—gas septicemia and “foaming liver”—were also produced by these microbes, although possibly in a less conspicuous form. Acid intoxication was produced in a rabbit inoculated with a culture of *Vibrion septique*. They found little to support the theory that the percentage of sugar is responsible for the predisposition of wounded muscle to gas gangrene infection, and were

able to show by experiment that the addition of glucose to serum did not exert any constant or marked favoring influence upon the growth of the *Bacillus* of Welch. Wright and Fleming point out that in a consideration of the symptomatology of acidosis, all known forms of the condition must be taken into account. The constitutional symptoms are hyperpnea and the possibility of sudden death. The treatment recommended is as follows: intravenous injections of alkali, followed in cases where there is danger of a relapse, by lactate of soda, administered by mouth in doses of 8 g. four-hourly until the urine becomes alkaline. The probability of an associated streptococcal infection, however, must not be forgotten. Nitrous oxide with oxygen is the best anesthetic; warmed ether is to be preferred to chloroform. It is of fundamental importance that all corrupted lymph be removed from infected or “acidosed” tissue in the after treatment of wounds, and that this lymph be replaced by lymph normal in alkalinity, in sugar content, and in antitryptic power, and to this end resort must be had to a local lymphagogue.

3. Note upon a Helpful Diagnostic Sign in Ruptured Digestive Ulcers.—R. J. Willan draws attention to the presence of a transverse ring of constriction across the abdomen at the level of the lower margins of the ribs and extending into the flanks on either side as a helpful diagnostic sign in cases of perforated digestive ulcer. The constriction does not disappear with general anesthesia, but does disappear when that condition has advanced to the stage of general abdominal distension. There is no marked hyperesthesia and the patient is quite unconscious of any feeling of tightness at the site of the constriction. The appearance is as if the abdomen were constricted above the level of the umbilicus and below the transpyloric plane by an invisible rope, which represents the level of the lowermost limits of the costal arch and may be termed the “infracostal” line. The muscles involved are the two recti abdominis in front, with the external obliques, the internal obliques, and the transversales laterally. The constriction does not apply to the whole of the ilio-costal space, but only to its upper part. Willan points out that it is reasonable to assume that the powerful stimulating impulses of origin, the results of the perforation, are conveyed by the sympathetic fibers to the celiac plexus and from these to the spinal cord, when the whole nervous system is probably involved.

7. Mutton Bird Oil.—J. S. Purdy points out that the

oil extracted from the Sooty Petrel is not only an excellent substitute for cod-liver oil, but, in the opinion of some, more effective in the treatment of bronchitic conditions and phthisis. This bird is known in New Zealand and Australia as the mutton bird. It spends nine months of the year in the Antarctic, and is constituted to stand extreme degrees of cold. On the same day every year the birds arrive in enormous numbers at their breeding places on Stewart Island, to the south of New Zealand, and on the islands in Bass Straits. They depart in flocks at the end of their period of migration. The female bird lays only one egg, which is hatched by the parents sitting in turn. The young birds are fed by the parents with marine life collected from far at sea. When about six weeks old the young, which are found in burrows similar to rabbit holes, are taken by the residents and half castes who visit these islands for the mutton bird season. The young bird is lined with fat, which is expressed as oil. The birds are then gutted, salted, and smoked, and used to be sold in Tasmania and New Zealand at a retail cost of one and a half to two pence (three to four cents) each, and in Sydney at six pence each. Recently a certain number have been tinned for export. Some have reached the western front, and have been much appreciated as an article of diet. The supply of oil from this source is considerable, and would be a valuable addition to medicinal oils. A special report on the mutton bird industry was prepared for the Tasmanian Government and arrangements have since been made for the sufficient protection of the birds to prevent any serious diminution in their numbers.

The Diagnosis of Primary Nasal Diphtheria and Cutaneous Diphtheria in Children and Infants.—L. Landé has met with 92 instances of primary localization in the nasal mucosa out of a total of 222 cases of diphtheria. Thirty-one of the children were less than one year old; from 4 to 13 years of age this form was not uncommon. In the infant more than 75 per cent. of cases of diphtheria develop primarily in the nose and remain isolated to the mucosa. The diagnosis should be based not only by the presence of the K. L. but by the special type of nasal discharge present, as well as the presence of fibrinous false membranes discovered by anterior rhinoscopy. The evolution of the process is usually mild, and an injection of serum will clean up the mucosa in from four to eight days. Cutaneous diphtheria is less well known, but Landé has, nevertheless met with 44 cases out of a total of 200 diphtheritic children, and in 32 cases it was even the only manifestation of the disease. It is far from infrequent and is dangerous from the viewpoint of contagion, because it may not give rise to any suspicious symptom, without fever or change in health. Clinically it appears as superficial, pseudo-membranous cutaneous erosions, and it may assume the form of ecthyma or a non-suppurating panaris, or even that of vericella or pemphigus. The prognosis of primary cutaneous diphtheria is good when the lesions are localized. Serum has a more rapid action even than in nasal diphtheria.

Malformation of the Cribriform Lamina of the Ethmoid Bone as a Cause of Purulent Meningitis.—C. Froboese recalls Hausemann's opinion, which admits that from the effect of shell explosions and the super-pressure resulting the cribriform lamina of the ethmoid may be driven in and secondary ascending infection of the meninges result. The variations in the thickness of the bone unquestionably give rise to a more or less great predisposition to this accident. The writer met with a case in which a malformation (perforation) of the cribriform lamina, with hernia of the dura, gave rise to a mistaken diagnosis of a polypus and led to an operative interference for the supposed polypus. A fatal purulent meningitis followed as a result of the mistaken diagnosis.

The Question of Prostheses Functionating at the Will

of the Patient.—A. Bethe studies the various methods of construction of artificial hands. Hands having a complicated mechanism are not suited for work requiring much force (laborers, farmers, etc.). In the finer trades the hand should adapt itself to individual needs. At present it may be admitted that Sauerbruch's kinetic procedure is far superior to the older principles of Ballij or Carnes. Modern construction of artificial limbs admits the necessity of a stop-cog for fixing the hand position for holding, no matter upon what principle the apparatus is based. It has been upheld by some that by this system the sensation of strength is done away with, since the muscle which starts the movement does not act in maintaining it. The advantage of this mechanism resides in a great economy of effort when carrying heavy objects, etc. Bethe admits the utility of perception of the developed effort, just as a man with an amputation stump locates the nervous irritation in the amputated limb, the wearer of an artificial limb finally locates the sensations in the false member. Even the sensation of force, resistance and of contact are in reality perceived in the stump to which the prosthesis is attached. It is to meet this end that Bethe has constructed an artificial hand on which the stop-cog, useful for heavy work, can be instantly removed, thus permitting the utilization of the hand for more delicate work.

The Abortive Treatment of Acute Articular Rheumatism.—A. Edelmänn adds to an intensive salicylic treatment the exhibition of sterile milk subcutaneously, thus realizing hyperemia of and exudation over the involved structures, and at the same time a concentration of the salicylate in the circulation. The rheumatismal process is thus controlled in a few days and the endo and pericardiac complications are prevented. Of seventy cases treated, the writer did not meet with a single case of pericarditis, and in only two patients did a cardiac lesion arise. This treatment is successful where the salicylate treatment alone appeared to be ineffective. A declared endocarditis is not a contra-indication for this treatment; on the contrary, it is favorably influenced by intramuscular injections of 10 c.c. of sterile milk.

Grashey's Radioscopic Operative Technique.—Drüner points out the services derived from Grashey's apparatus for the removal of foreign bodies (Grashey, Beitr. Z. klin. Chirurgie Bd. 70, Heft 1). This apparatus consists in a cryptoscope, through which the operator observes with one eye and can follow the steps of the operation on the screen, while with the other eye he can observe the entire field of operation by using daylight. By means of this method Martin has been able to remove 176 foreign bodies out of a total of 178 cases, a percentage which cannot be attained by any other method for locating foreign bodies.

The Treatment of and Vaccination Against Typhus Fever by Means of the Proteus X 19 Vaccine.—R. Hilgermann and W. Arnoldi admit that this bacillus enters to a certain extent in the etiology of typhus fever. Even by admitting only a semi-specific rôle, there is reason to look for a certain useful effect from vaccination with the Proteus X 19. The writers have observed that intravenous vaccination with this organism in the first place produces a reaction of an anaphylactic type, and then a drop in the temperature which indicates recovery. The writers, however, did not have a sufficient amount of the vaccine to enable them to make categorical statements as to results.

The Epidemiology of the Shiga-Kruse Type of Dysentery.—Von Friedreich has observed a clinically mild epidemic of this affection, in as much as 100 per cent. of the patients recovered. Regardless of this fact, the stools contained hypertoxic bacilli, and the reaction of agglutination was marked in most cases. The writer insists upon this discord being the clinical manifestations and the bacteriology of the epidemic, and rather tends to attribute it to the fact that the men were at the time living in very good hygienic conditions and had not been weakened by service at the front.

Book Reviews.

A TREATISE ON REGIONAL SURGERY BY VARIOUS AUTHORS. Edited by JOHN FAIRBAIRN BINNIE, A.M., C. M., F.A.C.S., Kansas City, Missouri. In three volumes. Vol. II. Octavo of 656 pages, with 213 illustrations. Price \$7.00. Philadelphia: P. Blakiston's Son and Co., 1917.

THIS volume impresses us as being distinctly better than the first. In our review of the first volume we said that each chapter was written by a surgeon particularly qualified in that field, and while that was quite true, there was a big difference between the best and the poorest chapters in the book. We suggested that some would have been better for a little friendly editing on the part of Binnie; but some reviewers, we find, were much more emphatic in their criticisms along this line. The second volume, however, seems much more evenly balanced and practically all the articles are at least good, while many are excellent. The list of contributors contains the names of some of the best-known surgeons of Great Britain and America; and it is safe to say that even the most critically inclined reviewer will be unable to point out more than one really weaker chapter in this volume.

British authors who have contributed to this volume include Rutherford Morison, who writes on the stomach and small intestine; F. T. Paul, who covers intestinal obstruction; E. Hurry Fenwick, with a section on the bladder; Alexis Thomson and William Thornburn, who cover the affections of the spinal column, and diseases of the spinal cord, respectively. American authors include Binnie, Ochsner, W. J. Mayo, C. A. Powers, E. S. Judd, L. L. McArthur, Coffey, Haggard, Lower, Gibson, and E. O. Smith.

Morison's article on the stomach and small intestines is excellent, but too little emphasis has been given to the value of the x-ray in the diagnosis of certain conditions, gastric, and duodenal ulcer, particularly. Binnie's description of sliding hernia could be made much more lucid, and this should be done with the first revision of this volume; for the operator who is confronted by a hernia of this type and does not thoroughly understand its mechanism and the technique of its reduction is apt to either cut into the lumen of the bowel or so injure its blood supply, while thinking he is separating adhesions, that gangrene may result. Ochsner's section on appendicitis gives a very complete exposition of the subject. For example, under the heading "Differential Diagnosis," thirty conditions, which may be confused with appendicitis, are considered. His ideas regarding the conditions under which an acute appendicitis should be operated upon are, however, somewhat at variance with those of most equally expert surgeons; though many will agree to his conclusions when operation must be done by a relatively inexperienced operator. The sections by Mayo, Paul, and Judd satisfactorily conclude the portion devoted to the gastrointestinal tract. Of the sections in the remainder of the book, those of Coffey (on the pancreas), Lower (on the kidney and ureter), Fenwick (on the bladder), and Gibson (on the prostate) are of particular excellence. Most of the remaining sections are also worthy of special mention, but lack of space forbids.

The illustrations in this volume are almost uniformly good, while the colored plate showing the anatomy of the pancreas is particularly effective. There are numerous typographical errors, and various evidences of not too careful proofreading; but the meaning of the text is clear in all but a very few instances. If the standard established by this second volume is maintained in the third the complete set will be of unusual value.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles, etc. Edited by H. R. M. LANDIS, No. 3, Volume IV. Twenty-seventh Series. 1917. Price, \$2.00. Philadelphia and London: J. B. Lippincott Company.

THE clinics in this volume are perhaps not up to the usual standard of interest. Nearly all are devoted to surgical topics, and orthopedics and bone surgery predominate. Of the original articles that by Meroz

of Geneva, on primary tumors of the heart, is a good monograph. Beverley Tucker's paper on brain tumors is valuable as a pathological study, but of fifteen cases related all ended fatally but two. W. A. Steel appears to have cured five cases of pyemia and three of septicemia by the transfusion of immunized blood. The type of disease treated usually ends in death, although limited to chronic blood states.

The very large number of prominent clinicians now engaged in military work must greatly reduce the number of available papers of non-military character. If we bear this in mind we may say that the reputation of the clinics is being fully upheld.

MALINGERING, or the Simulation of Disease. By A. BASSETT JONES, M.B. (Lond.). Late Temp. Hon. Lieut. R.A.M.C., Welsh Hospital, Netley; Late Senior Surgeon, Cardiganshire General Hospital; Deputy Coroner, North Cardiganshire; Medical Referee to Various Insurance Companies; Formerly Medical Referee under Workman's Compensation Act, and Surgeon to Various Friendly Societies; Fellow of the Royal Society of Medicine; Fellow of the West London Medico-Chirurgical and the Royal Meteorological Societies; Co-Author of "Fibrositis"; and LLEWELLYN J. LLEWELLYN, M.B. (Lond.), Senior Physician, Royal Mineral Water Hospital, Bath (Attached to Second Southern General Hospital); Physician, Officers' Convalescent Home, Bath; Formerly Medical Officer of Durham County Asylum; Fellow of the Royal Society of Medicine; Author of "Arthritis Deformans," Co-Author of "Fibrositis"; Contributor to Latham and English's "System of Treatment," also to "Oxford Encyclopedia of Treatment," etc. With a Chapter on Malingering in Relation to the Eye, by G. W. BEAUMONT, Acting Ophthalmic Surgeon to the Bath War Hospital; Author of "Injuries of the Eyes of the Employed," "Problems in Prognosis," etc. Price, \$7.00 net. Philadelphia: P. Blakiston's Son and Co., 1917.

THE present war has brought to the front a subject which is greatly neglected in peace times. To be sure, prison physicians, psychiatrists, and insurance examiners are all more or less familiar with malingerers, but now that the world has been combed for soldiers, and these exposed to terrific strain, we find wholesale malingering. Artificially induced abscesses, sugar added to the urine, soap-chewing convulsive efforts, these are commonplaces in the big armies, and have been described in many papers. Jones and Llewellyn, however, have undertaken a monograph on the subject and produced an admirable work. After an exhaustive study of the subject as a whole, with its psychology and medicolegal aspects, the authors go into great detail in describing malingering in its relation to various systems of the body; this part of the book is systematic and thorough, no vague generalizations are indulged in, but the writers are specific and practical. In short, they exemplify their own doctrine, that a diagnosis of malingering must not be founded on incomplete examination, imperfect observation, or hasty inference. This work might well be added to any practitioner's library; to the military surgeon it is invaluable.

THE PRACTICAL MEDICINE SERIES. VOL. VIII. PHARMACOLOGY AND THERAPEUTICS. Edited by BERNARD FANTUS, M.S., M.D. Associate Professor of Medicine, Subdepartment of Therapeutics, Rush Medical College, Chicago. PREVENTIVE MEDICINE. Edited by WM. A. EVANS, M.S., M.D., LL.D., Ph.D. Professor of Preventive Medicine, Northwestern University Medical School. Series 1917. Price, \$1.50. Chicago: The Year Book Publishers.

WHETHER or not advances in the domains of pharmacology, therapeutics, and preventive medicine are more readily apprehended and appreciated than those in the other provinces of medical science, the fact remains that this volume is a better annual than the average. It may be purchased separately and should prove an excellent investment for the practitioner in whatever field of activity. It needs only the turning of a few leaves here and there to show that the compilers are not only well qualified for this kind of work, but evidently work from a sense of duty and pleasure combined.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting Held February 7, 1918.

FIRST VICE-PRESIDENT, DR. GEORGE D. STEWART, IN THE CHAIR.

THE program of the evening was furnished from the Camp Upton Base Hospital, Major J. Whitham, commanding.

Classification and Results of Treatment of Pneumonia at Camp Upton.—DR. RUSSELL L. CECIL spoke briefly on this subject. He stated that on Feb. 3, 1918, the 100th case of pneumonia was admitted to the Base Hospital of the camp. The health conditions at Camp Upton had been unusually good. It was not until the arrival of the colored troops from the South that there had been an increase in the morbidity rate of the camp. The incidence of pneumonia by months was October, one case; November, 4; December, 47, and January, 46 cases. The maximum number of troops in the camp was 35,000; the number of colored troops 3,500, or 10 per cent. of the whole number, yet 50 per cent. of the pneumonia cases occurred among this 10 per cent. This was explained by the fact that the colored troops came from a warmer climate and by the fact that measles had been epidemic among them. A number of the cases of pneumonia were secondary to measles. Of the 100 cases of pneumonia, 75 were primary and 25 secondary. Of the secondary cases, 19 followed measles, four mumps, and one each, German measles and scarlet fever. The case following scarlet fever and five of those following measles were streptococcus pneumonias. Dr. Cecil then presented a table showing the classification of the pneumonia cases according to the causative agent, comparing the Rockefeller series of cases with the Camp Upton series. This chart showed that the pneumococcus was the cause of pneumonia in 94.59 per cent. of the Rockefeller cases and in 67.79 of the Camp Upton cases; the streptococcus was the causative agent in 3.1 per cent. of the cases of the Rockefeller group and in 24.7 per cent. of the Camp Upton series; the influenza bacillus was the causative agent in 1.2 per cent. of the Rockefeller cases and in 2.2 of the Camp Upton cases; the Friedlander bacillus caused 0.6 of the Rockefeller series, while there were no cases in the Camp Upton series due to this organism. The *Staphylococcus aureus* likewise caused 0.6 of the Rockefeller group and none at Camp Upton; the *Micrococcus catarrhalis* was not found as the causative agent in any of the Rockefeller group, while it caused 5.4 per cent. of the Camp Upton cases. The pneumococcus group were classified according to the type of pneumococcus into groups I, II, III and IV. The incidence of these four types in the Rockefeller group and in that at Camp Upton was as follows: Type I organisms were found in 33.9 per cent. of the Rockefeller cases and in 27.9 of the Camp Upton cases; Type II was found in 31.9 per cent. of the Rockefeller cases and in 12.79 of the Camp Upton cases; Type III was found in 12.9 per cent. of the Rockefeller cases and 9.5 per cent. of the Camp Upton cases; Type IV was found in 24.9 per cent. of the Rockefeller cases and in 50.8 per cent. of the Camp Upton cases. The methods used in classifying the groups were the mouse inoculation method and the more recent glucose blood broth method of Avery, the mouse inoculation being used in 71 instances, the blood broth in 6 and both methods in 13 cases.

The average duration with each type was as follows: Type I, 7 days; Type II, 6½ days; Type III, 6 days; Type IV, 6½ days. There were a larger number of cases due to Type IV pneumococcus than in civil life, and the cases of this type were a little more severe than in civil life. There was an unusually large number of cases due to the streptococcus, the average duration of these cases being 5½ days. Of the 23 streptococcus cases, 24 per cent. were hemolytic and 76 per cent. non-hemolytic. Only 26 per cent. of the streptococcus cases occurred among the secondary pneumonia cases. Twenty per cent. of these were of the bronchopneumonia type and 80 per cent. were of the lobar. The mortality rate for the different types were as follows: Type I, 5.8 per cent.; Type II, 0.0; Type III, 16.6 per cent.; Type IV,

18.7 per cent.; streptococcus cases, 30.4 per cent. The *Micrococcus catarrhalis* cases were not of a severe type. In the treatment of these cases two types of serum were used. The Government supplied a Type I serum and a polyvalent serum (Mulford). The speaker said they had tried out one or the other serum in nearly all the pneumococcus pneumonias. The maximum number of serum injections given was six and the average number 2.2. The serum was employed in 77 per cent. of all cases. Of the Type I cases, 100 per cent. received the serum and of the Type II cases 85 per cent. received the serum; of the Type III cases 100 per cent., and of the Type IV cases 68.7 per cent. were thus treated. The patients were all given one-half a c.c. of normal horse serum several hours before the administration of the antipneumococcus serum in order to protect them against anaphylaxis. In many of the streptococcus cases as well as in the different types of pneumonia cases the administration of the serum was followed by a marked drop in the temperature, which appeared to be a sort of foreign protein reaction. As was shown in other groups of cases studied elsewhere the serum was most effective in pneumonias due to the Type I pneumococcus. In speaking of the complications met with in this series of cases, the speaker stated that the most frequent complication was empyema, 12.9 per cent. of the pneumococcus cases and 24.9 per cent. of the streptococcus cases having this complication. There were several cases of pneumococcus septicemia. There were a few relapses. Serum sickness occurred in about 25 per cent. of the cases, probably in more, but it was not noticed. It came on with varying intensity in different cases, showing itself by a rise in temperature, urticaria, pain in the joints, and a general feeling of discomfort, lasting a day or two. In addition to the cases of serum sickness there were two cases of acute anaphylaxis. The first of these occurred in a lobar pneumonia due to Type III pneumococcus. The patient showed no reaction to the preliminary dose of horse serum, but five minutes after receiving the intravenous injection of serum, he developed an intense dyspnea, became pulseless, and his sphinters relaxed. This lasted about twenty minutes, when he revived and went on to recovery. The second case of acute anaphylaxis showed no reaction to the one-half c.c. of horse serum, but after receiving about 50 c.c. of antipneumococcus serum he became cyanotic, respiration stopped, and he died. This was explained by the fact that he had received 100 c.c. of antipneumococcus serum intravenously two weeks before (without reaction) and had become so hypersensitive that the second preliminary dose of horse serum did not protect him. There should not have been such a long interval between the doses of serum. There was a mortality of 15 out of the 100 cases of pneumonia, which was an exceptionally good showing. The mortality among the white troops was 14 per cent., among the colored 16 per cent., and it occurred mostly among the empyema cases. After analyzing the fatal cases more in detail, Captain Cecil stated that the lessons to be derived from their study of pneumonia cases at Camp Upton were: (1) All pneumonia cases should be typed; it was a great advantage to know with what organism one was dealing. (2) Serum should be given to all Type I cases, for there was convincing evidence that the serum was of value in these cases, as shown by the drop in temperature and a subsidence of symptoms. (3) The serum should be given early in the disease. (4) In the streptococcus cases one should be on the lookout for empyema and as soon as pus was detected free drainage should be established.

Measles from the Standpoint of Military Medicine.—DR. F. J. HACKETT, in charge of the contagious wards, presented this subject. He stated that measles had been defined as an acute disease of the upper air-passages and skin. It should be classified as an acute disease of the upper respiratory passages. It was a disease of close association, more common in the winter months, the period of poorer ventilation, the time of year when there were larger gatherings in overheated and poorly aired meeting places. It was endemic in cities and infrequent in rural or sparsely settled communities. Since an army barracks provided nearly all the above conditions measles was a large problem in National Army cantonments. The conditions that appeared to play the most important rôles in its spread

and control were (1) character of the camp strength, whether urban or rural; (2) early recognition with prompt and efficient methods of sanitation—of inspection, quarantine and isolation, and finally hospital treatment. The examination of the weekly reports from the Surgeon General's office on "Disease Conditions Among Troops in the United States," especially in respect to the new admissions of measles in the various camps throughout the country, revealed corroborative facts. In the northern camps measles was not reported, except in sporadic instances until after the onset of cold weather in November. Again, in the cantonments in the vicinity of the larger cities or more densely populated sections of the country, the new measles admissions, from week to week, were few, while in the camps whose location would presume a large population of former residents of rural communities, the new measles admissions were high, in some camps being above 500 for the seven days. That measles appeared to be a distinctly urban disease was well shown by the experience in a neighboring camp, where previous to the arrival of a large number of troops from country districts, the new measles admissions were low; following the arrival of evidently non-immune troops, the measles admission rate shot up week by week. At Camp Upton the experience was very similar. During the fall and early winter there had been few measles admissions, while since Jan. 1, 1918, the white measles cases had amounted to approximately 25 per cent. of the total admissions, and it was found that with one possible exception, all of these men were born or raised in rural communities, and had acquired city residence at a comparatively recent period. Dr. Hackett emphasized the importance of the early recognition of measles cases and of keeping a close watch on troops sent from measles infected camps. Such troops should be inspected daily. Koplik spots were always looked for but were not seen, and did not seem to be an important symptom in the diagnosis of measles in the adults. As a further precaution, trains arriving at Camp Upton with colored troops from measles infected camps were inspected before the troops were allowed to detrain. Barracks were aired for at least two hours every morning and afternoon; beds and bedding were ordered exposed to air and sun for the same time and together with the clothing of the men were disinfected by being exposed to formaldehyde vapor for thirty-six hours and then again thoroughly aired. The common towel and drinking cup were prohibited; mess kits and all eating utensils were thoroughly boiled after each meal and personal cleanliness was urged on the men. The Y. M. C. A. hut was ordered closed, the Post Exchange was allowed to serve but two men at the same time, and the regimental infirmaries were kept free from visitors. At the Base Hospital, cases developing in the wards were sent to the Isolation Section and the ward quarantined for two weeks. The Registrar was immediately notified. He in turn notified the Division Sanitary Inspector who quarantined the organization to which the patient belonged, and from which he was admitted. Suspects were handled in an observation ward. In a white man a previous history of measles relieved the man from quarantine; in the case of colored soldiers the statement of previous measles was not considered of value. Among the colored admissions there was a previous history of the disease in 60 per cent. of the cases. It had been observed that measles cases returning to duty after two weeks in the hospital were easy victims of pneumonia; for this reason the Surgeon General's office, by a circular dated Dec. 10, ordered measles held on sick report two weeks longer than the usual quarantine period. Their measles cases were all treated in well heated and well ventilated hospital wards. Medical officers, nurses, and attendants took care of the cases with all antiseptic precautions. Approximately 750 cubic feet of air space was allowed to each patient. Later orders designed to diminish the incidence of post-measles pneumonia provided that wires should be arranged across measles wards and sheets hung over these so as to form a screen between each two patients. Medical officers, nurses, and male attendants wore caps, gowns, and masks. Floors of wards were gone over daily with a cloth wet with disinfectant. Under such conditions 60 cases of measles were admitted to the Isolation Wards between Sept. 1, 1917,

and Feb. 1, 1918. Medical treatment was purely symptomatic and a close watch was kept out for pulmonary complications. Of the 60 admissions, pneumonia, probably bronchopneumonia, but massive and simulating the lobar type, was met with in 17 cases, or 35 per cent. When pneumonia developed the patient was immediately removed to the measles-pneumonia ward where slightly more air space was allowed. This ward was now also sheeted and screened. The Type I organism was found in 11.7 per cent. of the cases; Type II was not found in any case; Type III was found in 5.8 per cent. and Type IV in 35 per cent. In 17.6 per cent. of the cases *Streptococcus viridans* was found, and the *Micrococcus catarrhalis* in the same percentage of cases. After discussing the complications in the pneumonia cases, Dr. Hackett stated that there was but one death among the pneumonia cases following measles. In closing he urged the importance of looking for and preparing for outbreaks of measles in all army cantonments whose population would be made up of residents of rural communities. Measles and post-measles pneumonia would receive the proper consideration only when isolation wards were built and ready for occupancy at the time of the arrival of the first troops.

Hyperthyroidism in the Recruit.—Dr. HARLOW BROOKS, Chief of the Medical Service, presented this contribution, in which he stated that in civil life he had considered hyperthyroidism almost exclusively a disease of women, and particularly of unstable women in their youth. One of the great surprises to which he had been treated since in active service had been the large number of cases of this type that had come under his observation as a member of the Cardiovascular Board of the 77th Division and in the medical wards of the Base Hospital. The British had described precisely the same condition under the heading "The Effort Syndrome" or as "D.A.H.," meaning "Disordered Action of the Heart." This group of circulatory phenomena formed an important and inseparable part of the still more uncertain condition known as "shell-shock," and it occurred to many people who had never heard the sound of the shell, but more particularly among those who most earnestly desired never to do so. Dr. Brooks stated that he did not wish anyone to conclude that he considered that he had made a discovery in regarding the symptoms in this group of cases as due to hyperthyroidism, for he believed it was the prevailing opinion among clinicians in active service. The most striking feature of these cases in nearly every instance was tachycardia, varying in degree. It was present alike in those recruits presenting themselves for initial examination and in those cases that reported later and after a considerable mead of drill and army routine might have served further to upset the mental, emotional, and circulatory equilibrium of these patients. The tachycardia was rarely accompanied by arrhythmia, even in cases of very marked degree, and polygraphic studies, except in instances accompanied by other vascular conditions showed, aside from rapidity, few other signs of abnormal action except that there were in the same cases under varying conditions usually great variations in the rate of systole. Closely associated with tachycardia was an objective and subjective throbbing of the superficial veins, notably of the carotids, of the brachials, and even of the femorals, while that of the aorta in moderately thin persons was quite evident. Naturally in polygrams this throbbing of the vessels was very striking, and they had found this graphic method often the most secure way of differentiating this condition from the throbbing vessels of an aortic incompetence. Under excitement instead of an increase in the systolic stroke there was a fall in the stroking power and this was more evident in the medium sized vessels, as the smaller ones seemed to contract while the larger vessels expanded in their arc of pulsation. Naturally with these symptoms and signs there was a wide area of apical pulsation so violent at times that an actual sucking sensation was produced on the palpitating palm at the diastole. The heart signs, because of their rapidity, were usually very difficult to analyze, but in a good many cases there was a soft systolic murmur at the apex, transmitted at times with decreasing intensity toward the axilla. With these striking signs of circulatory derangement there were many symptoms appar-

ently secondary to the tachycardia. The capillary return was always delayed. Patients complained bitterly of an oppressive bursting pain in the region of the heart, and one was often able to demonstrate areas of hyperesthesia. The pain sometimes reflected to the left or right arm or shoulder. Other symptoms were rapid succeeding flushing and paling, fainting and dizziness. The blood pressure was very low except in hypersensitive cases, and there was a notably low pulse pressure in most instances. Adrenalin caused an increase in the symptoms as had been noted by the British observers; in the writer's experience there was also apparently a hypersensitivity to thyroid, though he had not pursued this investigation far because of its evident danger. The nitrites markedly increased the symptoms and there was a general hypersensitivity to the vasomotor dilators. The symptom of tachycardia was not controlled by digitalis. The sedatives, notably the bromides, at times had marked relief. Next to the tachycardia the manifestations which seemed most striking were the numerous evidences of emotional instability, which was an invariable accompaniment of the disease. This was shown in emotional temperamental outbreaks, sometimes in epileptoid attacks, in bursts of passion, in tears, profanity, or perhaps in convulsive muscular spasms. There was an intense feeling of fear, apprehension, and terror, quite often beyond the control of the patient. Outbursts of emotion were likely to be followed by states of great exhaustion and prostration, in which the patient might appear to be *in extremis*. The neurovascular instability was further shown by the tache cérébrale, by dermatographia, by urticarial rashes, and by the almost constant symptoms of tremor. The types of nationalities chiefly affected by this syndrome were a very certain index of the strong emotional element in the disease. The Hebrews led with over 50 per cent. of the numbers which had come under the writer's observation, the Italians next, then the Irish, and least of all the Negroes, among whom, in about 5,000 recruits, he had seen but a single case, and that questionable. Breathlessness almost to dyspnea was manifest at times, but without signs of cyanosis or asphyxia. The temperature variations were small. The deep reflexes were excited, especially in the knee jerks. Most of the patients were above the average in mental acuity and the condition was lamentably frequent among promising material for non-commissioned officers. In about two-thirds of these cases one saw a very definite thyroid hypertrophy or at least a prominence of the thyroid. In some instances this amounted to an actual goiter; this was nearly always evident in cases that gave a history of some time standing. A very interesting factor notable in most of these cases and of very direct bearing on the question of the rôle which hyperthyroidism played in this condition was the very certain part that heredity played in this syndrome. A very considerable number of the cases gave a history of ancestral goiter, particularly on the maternal side. There was also in most instances a familial history of nervous instability, of hysteria, insanity, perversions, or of genius. Exophthalmos was present also in the long standing instances of this condition though few cases showed in any typical degree either von Graefe's or Stellwag's signs. Thus it might be seen that these cases presented, though in perhaps mild degree in some instances, all the cardinal signs and symptoms of true Basedow's disease. These patients endured the acute infections or slight surgical incidents very badly. Tobacco also produced in them much more serious symptoms than in the average. They had also noted what had also struck the British observers, namely, a distaste for alcohol. Rest was the one factor which relieved these patients and mental and emotional rest was second in importance. This in either instance might be accentuated by the use of bromides or the more powerful sedatives. In explaining the reason so many of these cases occurred among young men of draft age the speaker said that the rôle which emotional shock, fright or mental traumatism played in the activation of Graves' disease was too well established to admit of question. The emotional excitement experienced by the young recruit incident to his separation from home and friends and the worry over what must take place subjected the nervous system to an ordeal that imposed a great demand on the endocrines of the recruit. Added to these, the overeating, drinking, and sexual excesses in which

the young recruit indulged just before his departure also called for a superlative activity on the part of the thyroid. His early days in the cantonment served to accentuate these conditions. He was forced into a new and strange life with new and strange acquaintances, all also in a state of physical and mental unrest. Thus far the question had been as to whether or not these subjects had the making of soldiers in them. Many of the cases recovered under the really healthful and normal routine of the military camp. If in these persons a careful training was imposed, not too severe, until the recruit was prepared for heavy work, if the worry and strain were sufficiently relieved by reaction, games, and camp shows, these men, oftentimes of the finest spiritual and patriotic fiber, were certain to make good soldiers, but if they were unhappy, or overly heavy or premature physical work was imposed, the recruit might break either nervously or cardiac incompetence might ultimately develop. This he had seen in ambitious young men of the higher and more spiritual type, who had striven to excel in their work and studies and rapid advancement had found them unprepared for the responsibilities and worries.

Autoinoculation in Syphilis.—Dr. JOSEPH KLAUDER, of Philadelphia, in charge of the syphilis wards, read this paper, in which he reviewed the evidence that went to show that individuals infected with syphilis were susceptible to a second inoculation or superinfection with syphilis, not only during the period lapsing between the infection with syphilis and the appearance of the chancre, but also at periods shortly subsequent to the appearance of the primary sore. In the writer's analysis of 200 cases of chancre 24 per cent. were multiple; in some of these cases, according to the patient, the second lesion appeared subsequent to the first. McDonough gave 33 per cent. as representing the number of chancres which in his experience were multiple. Noble reported cases in the various stages of primary syphilis successfully superinfected with secretions containing the treponemata from the patient's primary lesion on a small area of scarification on the same individual. In from three to eight days following the inoculation he obtained positive results in some of which lesions the treponemata were demonstrated. The sterile water controls were negative. After the disease was well established as a systemic infection, that was in the active secondary period, many investigators had reported unsuccessful attempts to superinfect individuals. Ehrmann, however, had succeeded in superinfecting syphilitics in the secondary period, in one instance as late as six months after the appearance of the general eruption, the positive results appearing in five to ten days after the inoculation, and did not appear to be influenced by treatment administered before their appearance. According to the superinfecting experiments of Finger and Landsteiner, if general infection was not yet complete a typical chancre could be produced, but from the time that constitutional symptoms appeared it became progressively more difficult to succeed. During the secondary period the result has some resemblance to the secondary papule, while in the tertiary stage ulcerated or nodular syphilides, resembling tertiary were produced. To produce any effect at all in these later stages, large amounts of virus must be introduced. These investigators further found that superinfection was possible under certain circumstances in all stages of the disease. Superinfecting experiments on syphilitic individuals were harmless and might be performed with impunity, and if successful in no way influenced the subsequent course of the disease. The writer stated that in a subsequent paper he would report the results of his superinfecting experiments on syphilitic individuals in various stages of the disease. In these experiments the treponemata from the individual's open lesion and from other sources were used. A study of the histological changes produced by such inoculations, and of results of agglutination of the same individual's serum with the treponemata used to superinfect was made. The writer reviewed the superinfection experiments of Neisser in monkeys, and the experimental work of Zinsser, Hopkins, and McBurney on animals from which they concluded that the resistance which developed during the disease was an expression of a localized tissue reaction as a result of an active invasion with the virus rather than as the result of an appreciable formation of circu-

lating antibodies analogous to those observed in bacterial diseases. Dr. Klauder reported a number of cases that were probably instances of superinfection with syphilis, and concluded that the subject of superinfection should be considered in the diagnosis of a genital lesion containing the treponemata when appearing in an individual giving a history of having had the disease. If in such lesions the treponemata were found in profusion and the Wassermann reaction was at first negative, later becoming positive, it was evidence of the lesion being a primary sore, a reinfection; whereas, if the treponemata were present in scanty numbers and the Wassermann was positive at the time of its appearance it was evidence of a possible superinfection. Genital lesions which he had observed and regarded as superinfections were papular ulcerative and ulcerating in type, with slight induration; they were clinically not chancre. It was probable that many so-called second attacks of syphilis, or reinfection, were cases of superinfection. There was nevertheless evidence that many so-called second attacks of syphilis might at times occur. By a second attack should be meant the occurrence, twice in a patient's life, of a primary sore followed by secondary symptoms, and if this definition were accepted the phenomenon would be rather rare. In the differential diagnosis of a genital lesion of the nature herein considered, besides reinfection and superinfection, the following possibilities should be considered; ulcerative processes over foci of syphilitic lymphangitis on the penis might in rare cases simulate a recrudescence of the primary sore; a mucous patch or an abrasion; in these, however, the treponemata were present in large numbers; a localization of treponemata at the point of lessened resistance as the result of trauma. Trauma in a syphilitic subject was often the determining point for the development of gumma.

Dr. SIMON BARUCH said he thought he might throw some light on Dr. Brooks' paper by mentioning the fact that in his experience at the Vanderbilt Clinic, the Riverside Hospital, and other institutions in the city, he had seen this same type of cases with enlarged thyroid and the same type of nervous instability, and had observed that the mental condition was responsible for intensifying the symptoms. Such individuals might be going along fairly well when suddenly they would be subjected to some great nervous or emotional strain and immediately this would bring out the more active symptoms of thyroid disease.

Dr. WILLIAM P. NORTHRUP spoke of the unusual opportunity that a camp hospital offered for the study of large numbers of cases under complete control, together with the possibility of making post-mortem observations. He said he had been particularly interested in Dr. Hackett's paper on "Measles" as he had been trying for twenty-eight or thirty years to keep it out of hospital wards and had found it a difficult thing to do. He asked whether they had tried the open air treatment of measles. It was a well known fact that measles usually occurred where there were large groups of children in one building and where frequently new groups were brought in. When an epidemic once started in a large institution it seemed that nothing would stop it until it had run its course. Dr. Freeman, in order to see whether he could keep these children with measles from having pneumonia, empyema, middle ear infections, and also to keep them from spreading the infection, had tried keeping them in the open air. He found that the results were much better with the children treated in the open air than with those treated indoors. When a case of measles occurred among the Indians it was customary to place the patient in a tightly closed tent and to keep a pot of water boiling with a brick in it. The result of this treatment was that nearly every case of measles died. Dr. Northrup said that he quite approved of Dr. Hackett's definition of measles as a disease of the upper respiratory passages, since such a definition centered attention on the symptoms of the upper respiratory tract which were manifest before the rash appeared. It would be interesting to know with the large opportunity at hand whether they had made any comparison as to the results of treating measles in the open air and in a warm room.

Dr. WILLIAM M. LESZYNSKY expressed his interest in Dr. Brooks' description of hyperthyroidism in the soldier. He said that from his observations he felt confi-

dent that it was the emotional strain rather than a disturbance of the thyroid secretion that was responsible for the symptoms described. Many of these men, who were under observation would never reach the other side, and he could not help feeling that it would be an advantage to the Government if they did not get over, because men showing this instability would be more likely than others to suffer from war neuroses. It would be interesting to know what percentage of these men were found to be suitable for the army when the tachycardia had disappeared.

Dr. BROOKS replied that a small percentage became fit for army service and that many of them might be found to be useful in other work that would be helpful to the Government.

Dr. HACKETT, in reply to Dr. Northrup's question, said that they treated all measles cases in a warm ward, and at the same time all measles wards were well ventilated. He believed their low death rate for measles was due to this treatment. They had had one man with measles who developed a complicating *Micrococcus cattarrhalis* pneumonia in a poorly warmed ward. He was transferred to a warm ward and the improvement which followed was remarkable. Measles in the adult always did better in a well warmed and well ventilated ward, and the incidence of pneumonia was much less when the wards were well warmed.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, January 23, 1918.

THE PRESIDENT, DR. FRANK C. HAMMOND, IN THE CHAIR.

The Pathology of Goiter.—Dr. A. G. ELLIS in this paper considered a few general points of the pathology of goiter. Diagnosis and treatment, he said, were based upon the size of the goiter and the evidence of perversion of thyroid function rather than upon the exact pathology of the individual gland. In other words, size, contour, density, movability of the goitrous thyroid did not give trustworthy information regarding histology. Clinicians with large experience reported that the symptoms were indicative of the structure of the thyroid. The Mayo Clinic, he stated, apparently reached the greatest accuracy in this respect. McCarrison, however, claimed that Graves's disease might exist with any form of goiter, and many others believed that this affection had no specific histology of the thyroid. The point to be remembered was that those whose experience included dozens or scores of cases should be careful in their criticism of conclusions based upon hundreds or thousands of specimens. Dr. Author's limited study of goitrous thyroids had not led him to believe that the pathological anatomy was easily predicted from the clinical symptoms. This referred especially to the exophthalmic goiter, which had the most striking symptomatology. Dropping the idea that each symptom-complex in goiter had its specific thyroid structure, Dr. Ellis thought the findings not to be so disquieting. The nomenclature of the histology of goiter he regarded as varied and confusing. Clinically goiters might be divided into the non-toxic and the toxic. Those of the first group were of chief importance from the standpoint of influence on neighboring structures. Termed simple or endemic goiter, they included parenchymatous, colloid, cystic, and some of the adenomatous forms. These types he thought were possibly very largely but different periods in a clinical process marked by atrophy of essential cells and lessened function. Treatment was based upon symptomatology; and rules regarding the handling of local tissue overgrowth of all types were applicable. Differentiation from true malignant tumors of the thyroid was sometimes difficult. Chief among the toxic goiters was the exophthalmic form with its well-known but not always constant symptom-complex. The clinical features rather than the microscopic picture of the removed thyroid should be the deciding point in the classification of this type of thyroid. Some of the adenomatous goiters, he said, belonged to the toxic group. The character of the colloid content, in his opinion, determined the toxicity of the goiter. The point of emphasis was that treatment of the individual

case of goiter was to be guided primarily by the local or systemic accompaniments, and secondarily by the fact that there was present a colloid, cystic, adenomatous, or hyperplastic thyroid. There should be, however, as accurate information as possible regarding the structure of diseased thyroids and a correlation of clinical findings with the pathology of every removed goiter in the endeavor to determine the changes in the gland producing certain symptoms. Such knowledge might be an aid in diagnosis and treatment, and a step toward the elucidation of the cause of goiter. Regarding etiology, reference was made to McCarrison, who believed that endemic goiter was an infection, and that the organisms reached the alimentary tract through infected soil, water and food. Animal experimentation seemed to substantiate this view. Exophthalmic goiter was also believed to be of infectious origin, although not so definitely so as the endemic type.

Goiter from the Standpoint of the Internist.—Dr. JAMES M. ANDERS said that in the discussion of goiter the point to be stressed was that really useful information was to be gained from a few recorded cases accurately and thoroughly studied rather than from the many superficially observed. While the principal symptoms of the disease were apparently due to the overactivity of the thyroid gland, cases were seen to develop in the course of other toxic conditions. The writer had observed two well marked instances secondary to rheumatism in which cure had been effected by the use of the salicylates. Cases, he stated, were recorded of luetic origin which had been cured by the antisiphilitic agents. The majority of cases of exophthalmic goiter were probably caused by nervous perturbations, especially in subjects predisposed by neurotic inheritances. Pregnancy and childbirth also had a causative influence, to be followed, however, by diminished function of the thyroid gland after parturition. An intermittent hyperthyroidism of minor degree was that occurring in adolescent girls. The claim had been made that this type might occur without alteration in the size of the gland; such cases usually yielded to appropriate measures if the condition were recognized sufficiently early; otherwise, severe toxic symptoms might supervene and persist. In exophthalmic goiter the degree of enlargement was moderate, as a rule, and the right lobe, usually more swollen than the left. The “swirling” murmur audible on auscultating the thyroid was highly characteristic when present. It may be absent. In the author's experience, tenderness, emphasized by Kocher as a finding in this disease, was not invariably present. Exophthalmos, sometimes a late appearing symptom, he had found to be a prominent feature, although subject to variations. Among other ocular characteristics were Von Graefe's, Stellwag's, and the Kocher-Boston signs. These signs, however, were more or less inconstant, although Von Graefe's was usually present. Muscular tremors, involving especially the hands, were almost constantly present and of much value for diagnosis. The characteristic features of neurasthenia appeared in classical cases. Kocher had claimed that leucopenia was an early and important sign. Dr. Anders' own experience confirmed this opinion in certain cases only. In his complete clinical records of 33 private cases, of which 27 were females and 6 males, 7 gave a previous history of tonsillitis and 6 of rheumatism. In one instance goiter developed immediately after an attack of acute tonsillitis and in two during acute rheumatism. One case was distinctly associated with chlorosis. This disease, assigned as a leading cause of hyperthyroidism, in his experience was of little etiologic importance. The family histories of his cases had revealed goiter in three instances only. The results of treatment, so far as could be learned, were: Cured, 11 (3 as a result of operation); improved, 12; unimproved, 2; died, 1. Dr. Anders regarded it a reproach to the medical profession that earlier diagnosis of goiter was not made than was at present the rule. In his opinion, the administration of iodine or thyroid extract in dubious cases, with a view to developing the symptoms, if the case were one of incipient Basedow's disease, was quite justifiable. He observed it to be a common experience among internists that rudimentary cases often yielded to well directed medical treatment. Those, however, which had reached a marked

degree rarely responded to any form of treatment other than surgical. The combined presence of fine muscular tremor of the hands and persistent tachycardia, he believed, justified a tentative diagnosis of this disease. Not uncommonly exophthalmos, or thyroid enlargement, or both develop, confirming the diagnosis. Persistent tachycardia with marked nervousness should always arouse a strong suspicion of this disease, and the same was true of tachycardia associated with the Boston-Kocher sign. Heart hurry might be the only feature present to be followed soon or late by the other characteristic symptoms of hyperthyroidism. The condition was frequently overlooked because neither exophthalmos nor thyroid enlargement had appeared. These two cardinal features, often late in development, were not uncommonly absent temporarily in fully developed cases of the affection. Rarely either or both of these signs might be permanently absent. From the standpoints of treatment and diagnosis an attempt should be made to distinguish the hypothyroid from the more common hyperthyroid form of goiter. In the former the gland might be slightly enlarged; was soft but not tender; without expansile pulsation to palpation, and no “swirling” murmur was audible. In this type the body temperature was slightly subnormal, the hands and feet liable to be cold and there was marked sweating on slight exertion. Bradycardia was the rule in hypothyroidism, the pulse rate dropping as low as 40 per minute. In these cases the use of iodine and thyroid extract were required—remedies which invariably tended to aggravate the symptoms of Graves's disease. Hyperthyroidism might merge into a myxedematous condition and it was important to note the development of the signs of atrophy or loss of thyroid function when they supervened. Not only were some of the classical symptoms often missing in hyperthyroidism, but it was also found that degrees of thyrotoxicosis varying from slight evidences of overfunctioning of the gland to the most profound signs of Basedow's disease, as shown by basal metabolic studies, occurred.

The Heart in Exophthalmic Goiter.—Dr. H. A. HARE said that goiter in the sense of simple enlargement of the thyroid gland was almost symptomless, except from pressure symptoms when the growth was exceedingly large. It was of the utmost importance to separate true goiter from exophthalmic goiter, and that there should be made also practically a third classification of thyroid disease, which might be called the hypothyroid class, because in these instances the gland, although it became greatly enlarged, did so without the development of symptoms indicating parenchymatous change. That is, there was encountered considerable enlargement of the thyroid gland, in which there was probably some degeneration of its secreting substance, producing hypothyroidism, although hyperthyroidism in the sense of the enlargement of the gland was present. In other words, there was one type of great enlargement of the thyroid gland which was symptomless, except from pressure. There could be enlargement so small that it was easily overlooked and yet in it there was so much secretion symptoms of hyperthyroidism resulted. There were also enlargements of the thyroid gland associated with lack of secretion, hypothyroidism, which class very frequently was overlooked. In regard to the hyperthyroidism or cases in which there was excessive secretion, so far as the heart was concerned, Dr. Hare had been surprised to find that in a considerable proportion of these cases, in addition to the tachycardia there was not present the relaxation of the vascular system. There was often found an exceedingly rapid pulse with a very high tension, that is, a pressure of from 160 to 180. While he had been asked to discuss the action of the heart in exophthalmic goiter, he felt that he ought to decline because of knowing so little about it. While the results of the administration of thyroid substance were known, there was very little knowledge of the definite physiologic action. In clinical medicine any acute disease with a pulse rate above 120 gave a discouraging outlook, yet in exophthalmic goiter cases of rapid pulse continued for years with impunity and often stood forms of stress and strain which were alarming. In regard to the matter of the heart in connection with surgical treatment, it was interesting to note that the surgeon in the end accomplished that which the physi-

cian wished to accomplish in the first place. The surgical treatment reaped the credit, while, as a matter of fact, the rest cure after operation was largely responsible. To the three types of hyperthyroidism should be added a fourth in which there was enlargement of the gland with excessive secretion, but in which the interlocking directorate of the other parts of the body compensated. This was seen in pregnancy. In the treatment the rest cure was invariably applicable in the presence of much tachycardia. There was little use in trying to treat an exophthalmic goiter patient who lacked the means of a real rest cure. Therefore, Dr. Hare believed that this type of case was properly sent to the surgeon earlier than the patient who could afford a rest cure. Concerning the action of drugs, he had had little result from digitalis. So far as the pulse was concerned, his best results had been obtained from veratrum viride in 8 to 10 minim doses of the tincture five to six times a day. A scientific explanation of these results, however, Dr. Hare said he was unable to give.

The Non-Surgical Treatment of Goiter and Its Complication.—Dr. CHARLES E. DE M. SAJOUS said that simple goiter should be regarded, in the light of modern knowledge, as the expression of a defensive reaction of the thyroid apparatus, as he had pointed out fifteen years ago, against one or more poisons of endogenous or exogenous origin. The pathogenic agent could be in the form of various organisms or toxins originating from the tonsils, dental abscesses, sinus or nasal disease, impacted or retained feces, etc. By penetrating the blood one or more of these poisons could awaken the defensive reaction of the organ. When the latter was physiologically normal, it did not become enlarged, but when through either heredity or local lesions due to diseases of childhood, etc., its efficiency as a protective structure was reduced to the bare needs of normal catabolic functions, any one of these numerous toxics placed what remained of normal glandular tissue under severe stress, with congestion leading to hyperplasia as the main result. If the tissues involved in this hyperplasia, *i. e.* those remaining in excess of the fibrous or other functionless tissues were able to carry on the defensive function, no symptoms of hyperthyroidism would appear and the condition remained one of pure goiter without systemic disturbance, but if the proportion of hyperplastic tissue exceeded this limit, the secretory activity of the gland was correspondingly increased and symptoms of hyperthyroidism appeared, with Graves's disease as an advanced phase. The treatment resolved itself into removing the cause. In true goiter, where pressure symptoms were present or sclerotic changes prevented reduction of the mass, surgical measure might become necessary; but where the growth was purely hyperplastic, elimination of the causative toxic, whether this might be tonsillar, peridental, intestinal, waterborne, etc., besides thyroid gland to aid the antitoxic process and relieve the gland of excessive work, excellent results might be obtained. In Graves's disease, with the same line of treatment with the vasoconstrictors and rest, a cure might be obtained in all but a very small proportion of cases. Dr. Sajous said that surgery was resorted to with unwarranted frequency in such cases.

The Constitutional Disturbance of Toxic Goiter as Influenced by Surgical Therapy.—Dr. CHARLES H. FRAZIER said that the present status of the surgical therapy of toxic goiter was but a stepping stone in the development of a method of arresting the toxic functional disturbances of the gland. The toxic goiter had claimed attention in increasing numbers yearly. His experience with the surgical treatment of goiter comprised 268 cases, 185 of which had been of the toxic variety. There has been 237 operations, including 147 lobectomies and 40 ligations. He enumerated four groups of toxic goiter, including: (1) The adolescent type, in which the hypertrophy was so compensatory that evidences of intoxication were trivial and operation was deferred. Later, however, this type might become extremely toxic and in young girls from sixteen to nineteen years of age presented the gravest form encountered; (2) a group met with between the ages of thirty and forty, in which the patient had had an adenoma for years and which had been trans-

formed into a toxic state. The prognosis of surgical therapy here was favorable; (3) a group in which the cases were toxic from the beginning, presenting the picture of exophthalmic goiter; (4) a group including any of the toxic varieties of comparatively long duration. Permanent relief here was not to be expected. Two group of cases to be carefully analyzed before operation is sanctioned were represented by (1) the patient, a woman with a small adenoma and a group of nervous phenomena; (2) the patient in which the condition was characterized chiefly by tachycardia and but slight enlargement of one lobe. In the first group, upon the two or three occasions when Dr. Frazier had been overpersuaded to operate, the outcome had not been gratifying; in the second group in his experience operation had been beneficial in about half of the cases. As a result of the observations by Means, the author stated that DuBois and others had demonstrated that the rise in basal metabolism indicated the degree of toxicity of the thyroid gland. Dr. Frazier said that he was employing this test not only to determine the degree of toxicity as an index of the operative risk and as a guide to treatment, but as a means of determining the ultimate effects of the operation. In his investigations of the thyroid he emphasized the possible relationship of the thymus gland. Clinically some extraordinary results, he said, had been reported following a partial thymectomy in hyperthyroidism. In the cases of mildly toxic goiter there were no contraindications to an immediate lobectomy without preliminary ligation. While operation could not be said to be imperative, there was a substantial basis for early operative interference. In the graver forms of toxic goiter the cases were all hazardous. In the earlier stages of the disease occasionally a lobectomy might be justified as the initial step of treatment; in cases of longer duration, under no circumstances should more than a ligation be attempted. In his clinic the usual time for doing lobectomy was two months after the ligation. The mortality in Dr. Frazier's series of operations upon toxic goiters had been 3.5 per cent. He found that of the constitutional disturbances, operation was most marked in its effect upon the nervous phenomena; next upon the nutritional disturbance. Upon the circulatory disturbance the effect of the operation depended largely upon the condition of the heart at the time of the surgical treatment. Tachycardia was the most persistent symptom. Concerning the amount of tissue removed, his inclination has been to increase the extent of the resection so that not more than one-sixth of the total amount was conserved. Using the term "cure" in the sense of restoring the patient to a state of health permitting the resumption of customary duties, although moderate tachycardia and nervous disorder might be present, he recorded 70 per cent. of recoveries. For the satisfactory end results of operation the surgeon was dependent upon the co-operation of the family physician.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

THE NATIONAL BOARD OF MEDICAL EXAMINERS.

Chicago, October 10-18, 1917.

(Continued from page 398.)

MEDICAL JURISPRUDENCE.

- (a) Define lunacy as legally recognized. (b) Name and briefly describe the varieties of insanity usually recognized. (c) What do you understand by "interdiction"?
- (a) Define the medicolegal importance of feigned diseases. (b) Give three (3) examples of feigned diseases and indicate the method by which each may be discovered or confounded.
- (a) Name one irritant poison, and give the symptoms or evidences found. (b) Give the mode of determining that death was due to such poison, including the postmortem findings.
- (a) What is the difference between a "material" and an "expert" witness? (b) Give an example of a hypothetical question.

5. (a) What is the function of a coroner? (b) Give brief outline of the procedure to be followed in examining a body supposedly dead of asphyxiation by illuminating gas.

HYGIENE.

Give the routes of entry and exit of the casual organism in each of the following diseases: mumps, syphilis, dysentery, cerebrospinal meningitis, malaria.

2. What rôle does environment play in the spread of disease?

3. Discuss the advantages and disadvantages, from the hygienic point of view, of milk as a food.

4. Outline the steps in the eradication of an epidemic of bubonic plague.

5. What are the public health duties of a physician?

6. Discuss the biological transmission of disease, and name the diseases so spread.

MEDICINE.

Answer ten of the following questions:

1. (a) Discuss the etiology of aortic insufficiency as it pertains to childhood, the adult, and the patient past 50 years of age. (b) Describe the murmur and vascular phenomena characteristic of aortic insufficiency. (c) What is understood by the incomplete types of angina pectoris?

2. Give the physical and other clinical signs required as a basis for a definite or probable diagnosis of pulmonary tuberculosis in the absence of the demonstration of tubercle bacilli in the sputum.

3. (a) Discuss the diagnostic signs of acute appendicitis and the indications for surgical treatment. (b) Give the diagnostic symptoms of chronic disease of the appendix.

4. (a) Discuss the clinical significance of nucleated red cells in blood smears (properly stained). (b) Define splenic anemia, and discuss its relation to diseases of the blood.

5. (a) Describe the urinary findings in chronic nephritis. (b) Discuss the causes of death in chronic nephritis.

6. (a) Discuss briefly the principles which govern the diet treatment in diabetes mellitus. (b) What are the criteria of improvement in this condition?

7. Outline in parallel columns the differential diagnostic signs of epilepsy and hystero-epilepsy.

8. In the case of a man 48 years of age with a right motor hemiplegia which came on suddenly following a short period of unconsciousness: (a) Discuss the several causes of this condition. (b) Outline the characteristic symptoms of the above. (c) Discuss the prognosis.

9. In the case of a child 6 months of age affected with summer diarrhea, give the method of arriving at a diagnosis, and outline a plan of treatment for the condition.

10. Given a case of a girl 8 years of age who is suddenly taken ill with vomiting, headache and a moderate fever: a laxative is given, but the fever continues with an increase in the headache and vomiting. Twenty-four hours later a thorough action of the bowels is obtained, but the temperature is still 102.6° F., pulse 112, respiration 24. The physical signs at this time are negative with the exception of some rigidity of the neck. State how you would investigate further, and give the plan of treatment according to the results obtained.

11. (a) Discuss the etiology of amebic dysentery. (b) Outline a plan of treatment for this condition.

12. Describe the characteristic symptoms of plague.

ANSWERS.

MEDICAL JURISPRUDENCE.

1. (a) *Lunacy* is "that state of disordered mind in which a person loses the power of regulating his actions or conduct according to the ordinary rules of society."—(Taylor.)

(b) "*The best classification for legal purposes*"; (1) Idiocy; (2) imbecility; (3) mania; (4) melancholia; (5) monomania; (6) general paralysis of the insane; (7) dementia; (8) certain forms of mania without distinct etiological relations.—(Dwight's *Medical Jurisprudence*.)

"Idiocy differs from other states of insanity in the fact that it is marked by a congenital deficiency of the mental faculties. There is not here a perversion or a loss of what has once been acquired, but a state in which, from defective structure of the brain, the individual has never been able to acquire any degree of intellectual power to fit him for his social position. It commences with life and continues through it."—(Taylor's *Medical Jurisprudence*.)

The dividing line between idiocy and imbecility cannot be sharply drawn unless it is assumed that idiocy is congenital or follows disease or injury in very early life; that imbecility develops among children and young adults; and that dementia is a condition associated with the aged. Both idiocy and imbecility may be easily differentiated from other forms of insanity, with the exception of dementia, by the diminished power of thought and by the absence of hallucinations, which are so prominent in cases of mania and the other more active forms of insanity.

In both *melancholia* and *mania* there is a general perversion of the mental faculties, but the former is usually accompanied with more or less depression, and the latter with more or less excitement.

Monomania or *paranoia* "is a form of insanity which comes especially under the class of degenerative diseases. It is essentially characterized by a delusion or delusions of a fixed and systematized character. They are usually indeed of one kind, and the disease has perhaps for this reason been called monomania. This is, however, an unfortunate term, as we find this symptom not infrequently in other forms of insanity, as melancholia, where we always observe decidedly fixed ideas of depression. The main fundamental characteristic of this disease is a delusion which has become a part of the belief of the individual, and which he believes himself able to explain and defend."—(Witthaus and Becker's *Medical Jurisprudence*, etc.)

General paralysis of the insane is characterized by both mental and physical symptoms. It most frequently follows alcoholism and syphilis, and is sometimes apparently the result of severe mental strain.

Its onset is insidious. The first symptoms are usually those of changed mental habit, irritability, fretfulness, soon followed by "characteristic delusions of grandeur," with the resulting extravagance both financial and conversational. This delusion may take the form of wealth or of power. Somewhat later the signs of mental degeneration become more apparent, and as the disease progresses the gait and vision are impaired. Violent and melancholic periods may alternate or they may be hardly noticeable.—(Dwight.)

Dementia, or, as it is commonly called, *softening of the brain*, is a term which is applied to a condition of mental enfeeblement gradually increasing until it reaches a stage of absolute mental decay.

(c) *Interdiction* is the legal restraint or commitment of the insane by judicial order.

2. *Feigned diseases are of medicolegal importance* because: (1) Soldiers, sailors, and prisoners may feign disease in order to shirk their duties or to secure a more comfortable mode of life. (2) Civilians may feign disease in order to shirk jury duty, appearance in court, or military service. (3) Such motives as fear, gain, notoriety or laziness, and especially the idea of extorting money from individuals, corporations, etc., may induce persons to feign disease. In such cases it may become the duty of the physician to ascertain the truth of the matter.

Feigned incontinence of urine may be detected by giving the patient an opiate at night and introducing a catheter during his sleep, or by taking him by surprise during the day and introducing a catheter, when it will be found that the urine has not drained off as it was secreted, but that the bladder possesses the power of retention. If the disease is real the prepuce and glans are pale and moist and the clothes have a urinous odor.

Feigned deafness may be detected by making a noise at an unexpected moment, or by a sudden change in the examiner's voice; administration of ether may enable one to detect the fraud, as before the culprit regains thorough consciousness he is apt to forget his rôle and "give himself away."

Feigned (amaurotic) blindness may be detected by observing whether the patient avoids obstacles placed in

his way; if the pupils contract perfectly the case is feigned.

In all cases the examiner should note the history of the case, the patient should be carefully watched unawares, and examinations made when the patient does not expect it (such as immediately after such a visit).

3. *Potassium hydroxide or caustic potash* is an irritant poison. The symptoms are burning pain during swallowing and an acrid, caustic taste. If the fluid penetrates to the stomach, there is persistent burning pain. Vomiting may or may not occur. When it does, the vomitus will usually be brown in color; it may or may not contain blood, and will simulate very closely in appearance that found after taking any of the strong acids.

Post-mortem appearances: The mouth, throat, esophagus, and stomach will be stained brownish or black. The mucous membrane and other tissues are more or less disorganized according to the strength of the solution. When the poisoning has been less violent in type and death occurs more slowly, ulcerations may be found extending even into the intestine.

Tests.—The characteristic soapy feeling and frothy appearance of materials with which caustic potash has come into contact will be noticeable. Potash may be detected in the form of carbonates, or otherwise by evaporating the suspected liquid to dryness and then heating the residue in a porcelain vessel sufficiently to char the organic matter. In the ash so remaining potash may be detected by the ordinary tests. When burnt in a colorless flame potash will give a violet color. (Dwight's *Toxicology*.)

4. (a) An expert witness may give his opinion on facts or supposed facts as noted by himself or asserted by others. *Theoretically*, this can only be done by one perfectly familiar with the subject in question; but *practically* any (or almost any) physician with a license to practice is accepted as an expert witness. A *non-expert*, or *material*, witness testifies only the facts which he has seen, or heard, or with which he has become acquainted by personal observation.

(b) *Example of a hypothetical question:* "Suppose a person, whose birth was premature, whose mother, while in pregnancy with that person, was greatly agitated in a voyage at sea; suppose that person, up to the age of eleven or twelve years, evincing no great intelligence, meets with an accident, the result of which is a series of surgical operations upon the head or upon the ear of that person; suppose that person subsequently entirely changes in character, habits, and disposition, imagines that he is pursued and chased by persons who have no existence; whose nights are sleepless, he frequently awakens with exclamations of his being chased, or that a person desires to kill him when he is not being pursued or chased, and no person desires to kill him; that on one occasion, being sent for a pitcher of water, he returns, drops without cause the pitcher at the feet of his mother and stands in great excitement and terror; when asked the reason of his emotion he declares that he has been pursued and chased by somebody; the same person was discovered on two occasions in a room at night, towards the middle of the night, crouched in a corner of the room muttering to himself, mumbling to himself in a state of great apparent terror, with beads of perspiration on his forehead; the question being put to him as to the cause of his emotion he does not answer or mutters or mumbles something incoherently; the same person has a conspicuous falling off of memory, is sent upon errands and messages, and mistakes in part or in whole the object of the errand or message—that is frequently the case; the same person is not steady, except in one instance, to any employment. This person altering in no particular degree or character his general habit of thought or life up to the age of nineteen, what would you say that these facts, if true and proven, indicated?" (New York Court of Appeals, First Division, Vol. 19, 1890.)

5. The function of a coroner is to hold inquests upon the bodies of persons found dead from violent, sudden, suspicious or unknown causes; in some States additional duties may be added. In examining the body of a person supposedly dead of asphyxiation by illuminating gas, the position of the body and surroundings should be noted, also the condition of the body, signs of violence, rigor mortis, lividity, the color of the blood

(carbon monoxide makes it of a bright, cherry-red color). If an autopsy is made the brain will be found congested and the respiratory organs tinged with blood; rose-colored spots are often found on the body. The coroner should also determine if the case is one of suicide or if a crime has been committed.

HYGIENE.

1. *Mumps.* The route of entry is probably by nose and mouth; the route of exit is in the buccal and (probably) nasal secretions.

Syphilis. The route of entry is through injured skin or mucous membrane; the route of exit is by the injured skin or mucous membrane.

Dysentery. The route of entry is the mouth; the route of exit is by the bowel evacuations.

Cerebrospinal meningitis. The route of entry is by the mucous membrane of the nasopharynx; its route of exit is by the mouth and nose.

Malaria. The route of entry is into the blood by the bite of an infected anopheles mosquito.

2. *Environment* is an important factor in the spread of disease. Until recently it was either not recognized, or else disregarded. But each year it is being accorded a more prominent place by the hygienist. Many diseases are due largely or entirely to the climate in which a person lives, the insects and animals that abound there, to the seasons, to the occupations in which he is engaged, to his home surroundings, quality and quantity of food, alcohol, injuries, etc. Overcrowding, impure air, humidity, extremes of temperature, the soil and water, disposal of waste, and many of the surroundings in which people live and work, are now being recognized as having an important bearing on the question of health and disease.

3. *Hygienic advantages of milk as a food:* Milk is a perfect food for the infant, and is also useful for the adult, it contains all the essential elements of a well-balanced diet, it is cheap, it is readily digestible, it can be modified in numerous ways, it is abundant, and can be obtained almost everywhere.

Hygienic disadvantages of milk as a food: "Milk is responsible for more sickness and deaths than perhaps all other foods combined. There are several reasons for this: (1) bacteria grow well in milk; therefore a very slight infection may produce widespread and serious results; (2) of all foodstuffs milk is the most difficult to obtain, handle, transport, and deliver in a clean, fresh and satisfactory condition; (3) it is the most readily decomposable of all our foods; (4) finally, milk is the only standard article of diet obtained from animal sources consumed in its raw state." (Rosenau's *Preventive Medicine and Hygiene*.)

4. *Management of an epidemic of bubonic plague:* "The handling of a plague epidemic is conducted along two definite lines of activity. One is to find and care for the human cases, the other consists in a warfare against rats. The organization and general management of a plague campaign do not differ radically from similar work in other epidemics. Cases of the disease must be sought for and early diagnosis confirmed; all deaths no matter from what cause must be investigated, and the body examined by an expert before burial is permitted. A bacteriological laboratory is a *sine qua non*. Cases of the disease should be isolated and the usual disinfection of excreta and surroundings exercised. Particular care must be taken that the isolation wards are vermin free. The place from which the case is removed should be given a preliminary disinfection with sulphur dioxide or other substance that may be depended upon to kill rats and fleas, and a search made in the neighborhood for secondary cases both in man and rodents. The campaign against the rat is expensive and difficult, but must be vigorously prosecuted to insure success. The rat warfare may be briefly summarized as a simultaneous attack upon the habitation and food supply of the rat; the destruction of rat burrows and nesting places; the separation of the rat from his food supply by concreting and screening such places as stables, warehouses, markets, restaurants, etc., the prevention of the entry of the rat into human habitations by the use of concrete, wire netting, or other barriers; and the use of poisons, traps, etc. All the rats that are caught in traps or found dead are brought to the bacteriological laboratory, where they are exam-

ined and careful records kept concerning the species, the location, the place where the rat was caught, the character of the infection, etc." (Rosenau's *Hygiene and Preventive Medicine*.)

5. *The public health duties of a physician* are to report to the proper authorities all cases of notifiable diseases occurring in his practice, whether the diseases are classed as communicable or occupational; and to protect as far as possible both his patients and the community from all diseases.

6. *Biological transmission of disease* means that the disease in question is transmitted by the bite of an insect which acts as the intermediate host for certain pathogenic protozoa or organisms of unknown nature. There must be a period of incubation in the insect. Diseases so spread, are: Malaria, yellow fever, and Rocky Mountain fever.

MEDICINE.

1. (a) *Aortic insufficiency in childhood* follows endocarditis which is associated with rheumatism, or chorea, or (chiefly) septic endocarditis (such as the pneumococcal and gonococcal forms). In the adult, it generally follows syphilis, coming on in about two or three years after the infection and being generally accompanied by pains of an anginal character. In patients over fifty years of age its onset is ascribed to the presence of arteriosclerosis.

(b) The murmur is diastolic, and is heard at the base of the heart and transmitted down the sternum towards the apex beat or into the left axilla. The pulsation in the superficial arteries is visible, and the pulse is characteristic—the Corrigan pulse. In some cases there is also a presystolic (Flint) murmur, heard at the apex. The aortic second sound is more or less replaced by the diastolic murmur; a loud sound may sometime be heard over the femoral and other large arteries. At times a double murmur may be heard over the femoral artery, if it is slightly compressed.

(c) By the term *incomplete types of angina pectoris* is probably meant all those forms of angina pectoris which have not the gravity of the true angina pectoris; such are pseudo-angina, neurotic angina, angina pectoris vasomotoria, and various toxic, hysterical, and reflex varieties.

2. In the absence of the demonstration of tubercle bacilli in the sputum, pulmonary tuberculosis may be diagnosed by: (1) *Symptoms*. "In the majority of cases there is a gradually increasing sense of languor or weakness, with some loss of flesh and pallor of the face, unaccustomed shortness of breath on slight exertion, chilly feelings, loss of appetite, perhaps some pleuritic pain, and digestive disturbance. Then slight fever and moderate night sweats may occur. There may or may not be slight cough and expectoration, and physical examination of the chest may be either practically negative or reveal signs of disease which are just sufficiently marked to be recognizable. The onset and manner of invasion may vary. The initial symptom in many instances is an hemoptysis, an occurrence which should be considered indicative of tuberculosis unless subsequently proved to be otherwise. Gastrointestinal symptoms, such as epigastric distress, acidity, eructations, flatulence, or vomiting, may be prominent. A regularly intermittent fever, with chills and sweats, is not uncommon. Pleurisy with effusion, or a dry pleurisy at one apex, occur not infrequently as early symptoms, followed at varying intervals by evidence of pulmonary involvement. Most commonly bronchitis, following exposure, initiates the disease. The cough continues and the physical signs of a localized bronchitis at one apex are found. In some instances the presence of tuberculous lymph glands antedates the pulmonary disease, which is often latent. In other cases the earliest symptoms relate to the larynx. Finally, the disease may be latent and progress even to cavity formation before the occurrence of symptoms (perhaps hemoptysis) sufficiently marked to attract attention; or it may be quite overshadowed by the presence of grave disease elsewhere.

(2) *Physical signs*: "The physical signs of the incipient stage may be at first negative or very indefinite, but sooner or later become plainly manifest. Inspection may show the phthisical chest, with deficient expansion, either general or limited to one apex. There may

be impaired resonance or slight dullness over an apex, more commonly the right. Auscultation over this apex shows the presence of fine, moist, crackling râles at the end of inspiration. The breath sounds are frequently interrupted or cogwheel, and feeble, or harsh and bronchovesicular, or the expiration may be high-pitched and prolonged. The voice sounds, especially the whispered voice, are transmitted with more than normal intensity." (Butler's *Diagnostics of Internal Medicine*.) Various tuberculin reactions and tests have also been used; and microscopic examination of the sputum may show the presence of lung tissue.

3. (a) *Diagnosis of acute appendicitis*: "When the three cardinal symptoms of the disease are present—that is, sudden onset of acute abdominal pain, followed by vomiting, occurring in one previously well; unilateral rigidity of the right lower abdominal wall; tenderness over the site of the appendix—the diagnosis of appendicitis is warranted in nearly every case. . . . Failures in diagnosis, however, may often be explained by the fact that the initial symptoms were insignificant, were lost sight of, or were obscured by the injudicious use of opium. The commencement of an attack of acute appendicitis may very closely simulate acute indigestion, in that there occur vomiting, colicky pains, often implicating the entire abdomen, and tenderness. But in acute appendicitis there is nearly always a certain sequence of symptoms—pain, vomiting, tenderness—and rigidity of the rectus muscle is nearly universal. If this sequence of symptoms—(1) pain; (2) vomiting; (3) tenderness—is altered, the diagnosis of acute appendicitis may well be considered doubtful; and where acute appendicitis is present and these symptoms have not occurred in the order described, other signs are generally present which render the diagnosis certain. Fever nearly invariably appears later than the three symptoms first mentioned. If hyperpyrexia occurs first, typhoid fever may be suspected, or pneumonia; if vomiting occurs first, acute indigestion or scarlet fever may be the cause; while where tenderness precedes the other symptoms for some hours or days, pelvic disease, or chronic intestinal ulceration are to be considered." (Deaver.)

The indications for surgical treatment vary according to the views of the surgeon. Some maintain that every case of appendicitis should be operated on as soon as the diagnosis is made. Others would operate only in case of rupture, or when suppuration occurs, or in cases which do not improve in a week or so or in cases which are steadily getting worse. Probably all would agree in taking out every appendix that has undergone more than one mild attack. Deaver says that "any form of treatment other than the surgical is to be considered only because extraneous conditions or certain definite contraindications, local or general, render it necessary to abandon or defer operative interference."

(b) *Diagnosis of chronic appendicitis*: "The plainer cases give a history of more or less constant distress or pain referred to the region of the appendix and examination reveals definite soreness on deep palpation over the organ. Even in the absence of any history of acute attacks a diagnosis may be made with almost invariable accuracy on this combination alone. The type and severity of the pain may be exceedingly variable. It may be sharp and stabbing, dull and aching, burning, colicky, constant, remittent, intermittent, or practically constant. It may or may not excite nausea. Intestinal flatulence is a common symptom. Slight stiffening of the overlying muscles as determined by light, careful palpation is a valuable confirmatory sign. Occasionally a thickened or distended appendix may be palpated, but less reliance should be placed on this than on a deep soreness on pressure which can usually be elicited." (Deaver's *Appendicitis*.)

In *chronic appendicitis*, there is a history of one or more previous attacks in which no operation was performed, or perhaps the diagnosis was not made; attacks of pain occasionally occur in the right iliac fossa; there are various digestive disturbances, such as constipation, diarrhea, flatulency; a tender mass may be detected on palpation over the painful area; the pain generally incapacitates the patient for a day or two.

4. (a) "Normally, erythroblasts are present only in the blood of the fetus and of very young infants. In the adult their presence in the circulating blood denotes

an excessive demand upon the blood-forming organs to regenerate lost or destroyed red corpuscles. In response to this demand, immature and imperfectly formed cells are thrown into the circulation. Their number, therefore, is an indication of the extent to which the bone-marrow reacts rather than of the severity of the disease. Normoblasts occur in severe symptomatic anemia, leukemia, and pernicious anemia. They are most abundant in myelogenous leukemia. While always present in pernicious anemia, they are often difficult to find. Megaloblasts are found in pernicious anemia, and with extreme rarity in any other condition. They here almost invariably exceed the normoblasts in number, which is one of the distinctive features of the disease. Microblasts have much the same significance as normoblasts, but are less common." (Todd's *Clinical Diagnosis*.)

(b) *Splenic anemia* is a condition of extreme anemia with enlargement of the spleen. The anemia is chronic; nucleated red cells may be found, particularly in the sinuses of the spleen; leukopenia is observed. The cause of the disease is unknown. The anemia is of the secondary type and never precedes the splenic enlargement, but follows it.

5. *"Chronic Diffuse Nephritis."*—The quantity of urine is diminished, it is cloudy from urates, the specific gravity may be high in the early, but is low in the later stages. Albumin is abundant, sometimes more so than in any other disease. The heavy sediment contains large numbers of nearly all the varieties of tube casts, hyaline, epithelial, granular, and fatty. The latter are especially characteristic. Occasional red corpuscles, many leucocytes, and numbers of degenerated epithelial cells are also found. The amount of urea is decreased.

"Chronic Interstitial Nephritis."—The urine is increased in quantity, light yellow, clear, with a persistently low specific gravity. Albumin is scanty, occurring in traces, and is sometimes absent. A few narrow hyaline casts are almost constantly found in the very small deposit. Cellular elements are as a rule no more abundant than in normal urine. Polyuria, persistent low specific gravity, and the presence of a few hyaline casts constitute the urinary signs of this disease. Albumin may or may not be present in small quantity." (Butler's *Diagnostics of Internal Medicine*.)

The cause of death in chronic diffuse nephritis may be exhaustion from inability to assimilate nourishment, from anemia or edema; cardiac weakness, uremia, or some complication.

In chronic interstitial nephritis, death may be due to coma, cerebral hemorrhage, intercurrent disease (as pneumonia), cardiac failure, dyspnea, dropsy, uremia; frequently a combination of uremic and cardiac conditions.

6. *Dietetic treatment in diabetes:* "The essential part of this treatment is complete rest of the alimentary tract so long as even a trace of sugar is found in the urine. The patient is, first of all, starved until his urine is free from sugar and for a further period of twenty-four hours. During this period water, tea and coffee may be taken. The next step is the arrangement of a scheme for diet, in which the intake of proteins, of fats, and of carbohydrates, and the bulk of the food have each to be determined. It is impossible to lay down hard and fast rules; each case must be considered separately, and the treatment made as individual as possible. The following outline of this method of treatment has been prepared by Dr. Joslin and is issued by him to his patients: *Fasting*—Fast until sugar-free. Drink water freely and tea, coffee and clear meat broth as desired. In very severe, long-standing and complicated cases, without otherwise changing habits or diet, omit fat, after two days omit protein and halve carbohydrate daily to 10 gm., then fast. *Alcohol*—If acidosis (diabetic acid) is present, take 0.5 c.c. alcohol per kilogram body weight daily until acidosis disappears. Alcohol is best given in small doses every three hours. *Carbohydrate Tolerance*—When the twenty-four hour urine is sugar-free, add 150 gm. of 5 per cent. vegetables, and continue to add 5 gm. carbohydrates daily up to 20, and then 5 gm. every other day, passing successively upward through the 5, 10, and 15 per cent. vegetables, 5 and 10 per cent. fruits, potato and oatmeal to bread, unless sugar appears or the tolerance reaches 3 gm. carbohydrate per kilogram body weight. *Protein Tolerance*—When the urine has been sugar-free for two

days, add 20 gm. protein (3 eggs) and thereafter 15 gm. protein daily in the form of meat until the patient is receiving 1 gm. protein per kilogram body weight, or if the carbohydrate tolerance is zero, only $\frac{3}{4}$ gm. per kilogram body weight. *Fat Tolerance*—While testing the protein tolerance, a small quantity of fat is included in the eggs and meat given. Add no more fat until the protein reaches 1 gm. per kilogram (unless the protein tolerance is below this figure), but then add 25 gm. daily until the patient ceases to lose weight or receives not over 40 calories per kilogram body weight.

Reappearance of Sugar—The return of sugar demands fasting for twenty-four hours or until sugar-free. The diet is then increased twice as rapidly as before, but the carbohydrate should not exceed half the former tolerance until the urine has been sugar-free for two weeks, and it should not then be increased more than 5 gm. per week. *Weekly Fast Days*—Whenever the tolerance is less than 20 gm. carbohydrate, fasting should be practised one day in seven; when the tolerance is between 20 and 50 gm. carbohydrate, upon the weekly fast day 5 per cent. vegetables and one-half the usual quantity of protein and fat are allowed; when the tolerance is between 50 and 100 gm. carbohydrate, the 10 and 15 per cent. vegetables are added as well. If the tolerance is more than 100 gm. carbohydrate, upon weekly fast days the carbohydrate should be halved." (Hughes' *Practice of Medicine*.)

Criteria of improvement are: Retention of body weight; obesity; the urine remaining without sugar; carbohydrate tolerance; and absence of fatigue, vomiting, restlessness, drowsiness, listlessness, nausea, vertigo, headache.

7. EPILEPSY.

Distant warnings: Few, mental.

Aura: More frequent, momentary, oftenest unilateral or epigastric.

Cause: None.

Onset: Always sudden, often with pallor, cry which is never verbal, immediate falling and complete unconsciousness, with rigidity, etc.

Tongue biting, frothing: very common.

Convulsions: Generalized, tonic followed by clonic spasms, very rarely tonic alone; flexor spasm predominates.

Reflexes: Pupils contracted at onset, dilated later, immobile (in clonic period). Tendon and skin reflexes absent during and after attack.

Involuntary evacuations: Frequent.

The urine: Solids always increased, both nitrogen and phosphates.

Temperature: Sometimes elevated, 2°-3°.

Coma: Complete.

Duration of seizure: Very short.

Postparoxysmal: Sensory and motor exhaustion, ecchymoses, absent reflexes, mental incapacity, with no memory of transpired events.

HYSTERIA.

Distant warnings: Frequent, emotional.

Aura: Less frequent, longer, bilateral, foot aura, globus.

Cause: Emotional.

Onset: More gradual, rarely with pallor or cry, which may be repeated or verbal, and recur. Rarely brusque falling, slower and less complete unconsciousness, and may react to suggestion.

Tongue biting: Exceptional, or seemingly purposive.

Convulsions: Rigidity, to carry out semi-intentional movement; struggling; clonic, irregular spasms; extensor spasm predominant, "arc de cercle," clownism.

Reflexes: Pupils usually wide and react (may be immobile, Westphal). Sometimes convergent strabismus. Reflexes rarely absent; or increased.

Involuntary evacuations: Absent or most exceptional.

The urine: Solids decreased; altered ratio of earthy and alkaline phosphates.

Temperature: Practically never elevated.

Coma: No real coma.

Duration of seizure: Longer, recurrent, relapsing.

Postparoxysmal: Depression, fatigue, pain in the head or stomach, nausea, some memory of attack.

—(Edwards' *Practice of Medicine*.)

8. *Complete hemiplegia* is caused by a lesion of the knee and anterior two-thirds of the posterior limb of the internal capsule; in this case the lesion is on the left side of the brain. In addition to the hemiplegia there may be retention or incontinence of urine and feces, the body temperature will be at first subnormal and then raised slightly on the paralyzed side, the pulse becomes more rapid; if the coma persists there will be a rise in body temperature and also Cheyne-Stokes respiration. The tongue protrudes toward the affected side, and there may be hemianopia and disturbance of hearing; there may be anesthesia on the affected side. Most cases are not fatal; a second attack is likely to occur within a few years, from which a few may recover; a subsequent attack is very likely to prove fatal.

9. *Summer diarrhea in infants. Symptoms.* In the mild form the stools are curdy, loose and foul. The fever is moderate, and the child fretful. The character of the stools soon changes to a greenish-yellow, and they become more numerous, five or six a day, and the fever rises to 102° or 103° F. If prompt measures are taken, recovery is rapid and quite certain. In the severe form, there is vomiting, and loose, frequent, green stools. Fever, inability to take food, with weakness, rapid emaciation and prostration soon follow. The pulse is weak, the fever high; the stools may contain mucus and be streaked with blood. Sometimes delirium and coma supervene. *Treatment:* Place the patient in the coolest, cleanest and largest room possible. A cotton slip and diapers only are to be worn. Secure a competent nurse if possible to intelligently follow orders. Reduce the fever by frequent cool sponging or tepid baths. If the temperature is above 104° F. and the pulse permits, use an ice-bag to the head. An initial purge with castor oil or calomel is indicated. Stop milk in all forms for at least twenty-four hours, placing the child on a starvation diet of boiled water alone or on barley water, made with one ounce of flour to the quart. If at the end of a day the frequent stools persist, continue the substitute feeding until a change for the better is noticed.

If barley gruel is not palatable or tolerated, one may try rice water or albumin water. In the case of nurslings resume the feeding at longer intervals preceded by a dram or two of boiled water. In artificially fed babies, resumption to cow's milk feedings must be made only when the stools resume the normal type. Whey or buttermilk feedings are serviceable substitutes. Begin with a modification lower than the original prescriptions.—(Chapin and Pisek's *Diseases of Children*.)

10. Further investigation should include an examination of the blood; if there is a leucocytosis, chiefly of the polymorphonuclear cells, it will point toward cerebrospinal meningitis; the *tâche cerebrale*, Babinski reflex, and Kernig's sign, if present, will also confirm the suspicion of the same disease. Lumbar puncture will clinch the diagnosis; in case of cerebrospinal meningitis the spinal fluid will be cloudy or turbid, and will contain the diplococcus intracellularis meningitidis, and sometimes also streptococci and staphylococci. *Treatment* consists of rest in bed, quiet, darkened room, proper nourishment, skilled nursing, bowels kept slightly loose; plenty of water should be ingested; the head and neck should be raised and supported on a pillow; warm baths and cold applications to head and neck are indicated; the main therapeutic measure is the injection into the spinal canal of Flexner's antimeningitic serum.

11. *Amebic dysentery* is endemic in the tropics. There are two species of amœbæ having man for a host; one of them, the *Entamoeba histolytica*, is pathogenic; the other, the *Entamoeba coli*, is harmless. The disease is spread by carriers who have the encysted amœbæ in their stools; and when these carriers are employed as cooks the risk of infection is increased. Flies are also believed to be capable of transmitting the disease. It is not at present believed that food, fruit and water are important factors in the spread of the disease except in connection with carriers. *Treatment:* The emetine treatment is considered specific for amebic dysentery. From one-third to two-thirds of a grain of emetine hydrochloride is dissolved in sterile saline solution, and given by hypodermic injection into the subcutaneous tissues. Colonic irrigation with saline solution, or with quinine muriate in dilution of 1:2000, has also been recommended.

12. *The characteristic symptoms of plague.* The face is pallid, anxious, or apathetic; the gait is staggering; there is a fever of an irregular type, the pulse is at first soft and rapid and afterward thready and irregular; pneumonia or broncho-pneumonia may be observed; cyanosis and dyspnea are present; buboes are found in the inguinal and axillary regions, and the cervical and submaxillary glands are also involved; these buboes are very tender, and the skin over them often becomes necrotic and sloughs; the liver and spleen may be found congested and tender.

(To be concluded.)

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

Miscellany.

WILL YOU SANCTION THIS?

BY REX BEACH

PRESIDENT AUTHORS' LEAGUE

CONGRESS—or a sufficient majority of it—has voted to destroy magazine reading.

It has accomplished this by passing a simple law reestablishing a postal "zone" system for all publications—a zone system and postal principle that was abolished by President Lincoln in 1863, and by establishing through a complicated system postal rates that mean increases of from 50 to 900 per cent postage increases to all periodical readers.

By this "zone" system American readers of periodicals—home, educational, scientific, business, or religious—are to be penalized by enormous postage increases on the weekly or monthly papers they read, and the greater their accidental remoteness from the city of publication the greater is the penalty that is placed upon them.

Magazines have been a slow growth. In the process of their development and evolution it has happened that publishing is chiefly concentrated

remote from city life. It is the magazine combined with rural delivery that has brought to the door of the countrywoman material which helps her solve problems needing advice more easily obtained by her city sister. Through this medium she has known current events, has guided her children by the educational influences offered, and has been able to keep herself in harmony with the world from which she was separated. Periodicals and newspapers are as essential as food to the country home.

"Then again the attractive magazines in every city home means keeping together the family circle. To make the magazine prohibitive by excess postal rates would be to take away from mothers one of the means whereby they have battled against outside attractions.

"Now just because a woman lives in a Western State remote from publishing centers—and of course home interests affect the woman most—is she to be made to pay a penalty in order to bring opportunities to

her door? To enforce the 50 to 900 per cent periodical postage law would be causing mental starvation to many who have only this means of keeping abreast of the times.

"Every thinking Eastern woman should put her full strength into a drive which will give her Western sister the same advantages which she enjoys."

And to this may be added the splendid report of the United States Postal Commission appointed in 1844 to determine the functions and purposes of the Post Office in relation to the people of our nation. The function of the Post Office was, it said:

"To render the citizen, how far soever from the seat of Government, worthy, by proper knowledge and intelligence, of his important privileges as a sovereign constituent of the Government; to diffuse throughout all parts of the land enlightenment, social improve-

ment, and national affinities, elevating our people in the scale of civilization and bringing them together in patriotic affection."

This was the purpose of the Post Office.

This 50 to 900 per cent postage increase on magazines is not a war tax. Publishers were already taxed by excess profits and income taxes. It is not a war tax; Postmaster General Burleson has so stated in his annual report when he declared it is permanent postal legislation—unless repealed through your protests to Congress and Congressmen. Will you write—telegraph—or urge the passage of resolutions of protest against this destructive law?

WILL YOU HELP?

Write to your Congressman, protest against this destructive law, and demand its repeal.

Get your club or association to adopt resolutions demanding its repeal.

Will you enroll to help repeal this law that penalizes periodical readers with heavy penalties?

If so, send your name and address—and a copy of any resolutions adopted—to

CHARLES JOHNSON POST
200 Fifth Avenue : : New York City

It means that hundreds of thousands of readers will be compelled to give up their periodicals owing to the terrific increase in their postage cost.

And the tragedy of this 50 to 900 per cent magazine increase postage law lies in the fact that this loss of readers will come from classes and from sections of our nation where widespread reading should be most encouraged—from people in remote sections where life is a bitter struggle on the margin of subsistence—where the habit of reading is just forming and the little weekly or monthly budget for magazines has but so very recently become recognized as an important item in family life. The terrific magazine postage increase will wipe these out. That is the real tragedy to this nation.

I could do no better than quote the fine words of a Western woman, Miss Arminda Wood, president of the Woman's Club of Racine, Wis.:

"The many splendid magazines published to-day," she wrote in an appeal to Eastern women from the women of the West, "are a means of education to many a home where other opportunities are lacking. And many of these homes are remote from publishing centers—many even

THE PREVENTION OF DYSENTERY IN ARMY CAMPS.

BY CHAMPE CARTER McCULLOCH, M.D.,
WASHINGTON, D. C.

COLONEL, MEDICAL CORPS, U. S. ARMY; LIBRARIAN, SURGEON
GENERAL'S OFFICE; PROFESSOR OF MILITARY HYGIENE,
ARMY MEDICAL SCHOOL.

DYSENTERY has no doubt existed from the earliest times. It is mentioned in the Papyrus Ebers (1600 B.C.). It was named by Hippocrates, the term meaning "bad bowels." Herodotus called dysentery the "war plague." In the army of Xerxes in 480 B.C. dysentery was very severe. It has often prevailed in epidemic form, especially following war and famine, and in jails, asylums, and crowded camps. According to Shiga, "always a constant companion of war, it has been more fatal to armies than powder and shot."

A modern French writer¹ says, "Bacillary dysentery is a scourge inseparable from the pathology of war. In all the epochs of history it has attached itself in a constant fashion to armies in campaign. The documents the most ancient show it raging among the troops engaged, and determining, from the time of mobilization, ravages assuredly more terrible than those occasioned by the fire of the enemy."

The English army, in 1415, was reduced to a quarter of its effectiveness by dysentery, and on this account had to be returned home after the battle of Agincourt.

In more recent times this disease was prevalent among Napoleon's troops in Egypt and in Poland. The "diarrhea of aggravated type" that gave so much trouble in our Mexican War was no doubt in large measure epidemic dysentery. In the Peninsular and Crimean Wars it was rife. In the Civil War of 1861-65 "dysentery and diarrhea" gave the largest admission rate of all diseases (600 per thousand per annum), and next to the largest mortality rate, being exceeded in the latter respect only by typhoid fever. It caused one death out of every 3.5 in that war. It is said that there were over a quarter of a million cases of dysentery in the Civil War. In the Boer War dysentery came second (next to typhoid) as a cause of death. While not very serious in the short Russo-Japanese War, it formed one of the largest sources of admission to sick report.

These instances could be multiplied indefinitely, but it is unnecessary to quote them further. The idea is no doubt clear to the reader. It will suffice, in this connection, again to quote Dopter, who con-

tinues: "Indeed, not a war has ever been waged in which dysentery has not scourged not only the belligerents but also the civil populations in the paths of the armies. Without being accused of exaggeration, one can affirm that all the great struggles of the seventeenth, eighteenth, and nineteenth centuries have been marked by its epidemic development, preponderating over that of all other infections."

It is only in the last half of the nineteenth century that we have secured definite knowledge of the etiology of dysentery and have been able to differentiate the amebic and the bacillary forms from each other. We now know that the epidemic form of jails, camps, and insanitary cities is bacillary in nature, and has occurred and may still occur in all climates, and that, on the other hand, the endemic form, that is almost confined to the subtropics and tropics, and principally to the latter, has a protozoal cause, the ameba. It was this latter form that caused us so much trouble during the early years of occupation of the Philippine Islands, and still claims its occasional victims among our soldiers there. The native Filipino seemed largely immune, but amebic dysentery has proved the greatest foe of the soldier and white American civilian in those islands; also of the English in India, and of the white man generally when he has attempted to colonize the tropics. In the early days in the Philippines in number of cases it came next to malaria, but much ahead of that disease in fatalities and in lasting disability, while we withstood without really serious involvement the cholera and the plague and the beriberi, which played havoc with the natives. We also had the bacillary variety there, but not great numbers of cases; this occurred nearly always in sharply defined small epidemics. Endemic (amebic) dysentery has as its principal centers India, the Malay Peninsula, China, Japan, and the Pacific Islands; Arabia, parts of Africa, and South America—in fine, the tropical and subtropical latitudes.

The dysentery that proved so serious in the Boer war was of the bacillary kind; the amebic form did not occur. In fact, the dysentery of history and that which has caused such havoc in warfare and in armies and camps generally was almost universally of the bacillary form. Of course, this is mixed up in the statistics with the ordinary simple diarrheas, but when very severe and disabling or fatal we can put it down without much chance of error as the real bacillary dysentery.

In all armies there has been a notably great reduction in the incidence of dysentery in the last few years, due to the marked improvements in general hygiene that have been recently instituted.

This decrease will not last, however, in active operations unless we keep strictly up to the mark our modern methods of camp hygiene, especially in regard to the establishment and care of latrines, and the warfare against flies. There has also been a notable decrease in epidemic dysentery among the civilian population in Europe and other civilized countries, due to improved sanitation. Its incidence in Europe before the present war was mainly institutional, except in camps.

There is no especial age or sex or race incidence in dysentery except for the apparent immunity of the native to the amebic form. It is more a disease of country districts than of cities, and of summer than of winter. Soldiers, sailors, and tropical explorers pay the heaviest tribute to it. Davidson says it is notably the poor man's disease.

As in all infectious diseases, adequate *diagnosis* is a necessary preliminary to any practically successful prophylactic measures. In dysentery our modern methods of diagnosis depend, first, on the history and symptomatology of the cases; secondly, on microscopic and laboratory methods of investigation.

Cases of amebic and bacillary dysentery when carefully studied show marked differences in the totality of the symptoms as well as in the history of their incidence. Amebic dysentery in the first place is, as above stated, endemic rather than epidemic in character. The clinical characteristics of this type, as distinguished from the other, are insidious onset, marked tendency to chronicity, relapses alternating with periods of comparative quiescence, great liability to abscess of the liver, and confinement to warm climates or the warm season of temperate climates. Whitmore describes it as usually subacute from the onset; McCaw says it is "insidious in its approach." Recurring attacks come on showing the clinical symptoms of pain, tenesmus, mucus and blood in the stools, and of greater or less severity. These attacks are, however, separated by periods, sometimes long, of complete absence of the local symptoms, indeed quite generally with a condition of obstinate constipation. The disease is not immediately fatal but tends to resist complete cure.

The bacillary form of dysentery on the other hand is epidemic in its incidence. It is a specific acute infectious disease, resembling the other type only in the local symptoms of pain, tenesmus, and bowel passages. It usually begins like the other acute infections—suddenly or with short prodromes of malaise or digestive disturbance. As McCaw says, the cases are abrupt and threatening from the beginning. It is a true infection or intense intoxication which generally terminates quickly in death or recovery, and only very exceptionally glides off into a subacute or chronic form. With the local symptom there is quite generally marked general depression, and other constitutional symptoms of great gravity. The mortality is high.

Thus, in identifying the type of the disease with which we have to deal, the history of the case and the circumstances attending it generally give us a pretty good line as to its proper classification. However, it will be readily understood that the only sure means of diagnosis is microscopical and bacteriological.

The definite diagnosis of amebic dysentery is made by finding the ameba in the stools. Sometimes it is easily found, again only with considerable difficulty. One picks out a fragment of the stool and compresses it under a cover glass; when the organisms are scarce, the watery stool resulting from a saline purgative may be examined. The stool should be fresh when examined and should be kept warm to keep up the motility of the parasite. It is unsafe, according to Whitmore, to try to diagnose the fresh ameba when it is quiescent. We differentiate the pathogenic *Entamoeba histolytica* from the non-pathogenic *Entamoeba coli* by the peculiar characteristics of the former—that it is larger, more active and contains red blood corpuscles.

Some authorities state that unless cysts are found (containing eight nuclei in *Entamoeba coli*, but only four in *Entamoeba histolytica*) the ordinary observer is not expert enough to distinguish with certainty between the microscopic appearances of the two forms. A difficulty here is that the cysts do not generally appear until towards convalescence, and that some facility with the technique of staining is required. Emulsifying the feces in Gram's iodine solution is, however, usually sufficient. Several examinations of the material are necessary before arriving at a negative conclusion. It is as a means of picking out "carriers" that the staining of the cysts is especially useful.* In doubtful cases the material may be fed to a young kitten or better injected directly into its cecum. The therapeutic test with emetine is occasionally of value.

In the bacillary form of the disease, laboratory diagnosis is more difficult and therefore less practical, owing to the more elaborate technique necessary and to the fact that agglutination phenomena do not appear until about the twelfth day. The only absolutely sure method of diagnosis is the isolation of the bacilli from the stools. This will no doubt be more practicable in the Army than formerly owing to the modern use of the motor field laboratory. One selects pieces of mucus from the stools and washes them thoroughly with sterile saline solution to remove other bacteria. These are emulsified in bouillon and a few loopfuls of the emulsion placed on some differentiating restraining medium such as Endo's lactose-fuchsin-agar. Resulting colonies are like those of typhoid, but the bacilli are non-motile. These colonies may be "fished" and subcultured and put through the usual tests, including planting upon the various sugar media. Agglutination reactions are of considerable value in determining the nature of the bacilli thus isolated and in differentiating the Shiga-Kruse strain from the Flexner-Strong and "Y" varieties. It will be recalled that the two latter, unlike the former, produce acid in mannite media. Stitt says that the therapeutic polyvalent serum can be used for diagnostic agglutination tests and that organisms, recovered from the feces and agglutinating in 1 to 50 or 1 to 100 dilutions, will confirm the diagnosis of bacillary dysentery as against the amebic form.

*It has been found by British investigators that at least 10 per cent. of soldiers returning from tropical service carry the cysts, irrespective of whether or not they have shown clinical symptoms.

The *prevention* of dysenteric disease is, as we have seen that history shows us, liable to be of the greatest importance in connection with our big new Army cantonments and camps, as well as in the billets and trenches on the other side of the water.

A brief general outline of our present day methods of attack may therefore serve to interest, or perhaps instruct, some of those civilian physicians now taking up army commissions, whose former professional work has not led them to look at this kind of problems from the army point of view. We may consider rational prophylactic measures against dysentery from two different angles: that is to say, first, the general sanitary measures that may be put in force, and, second, specific methods of procedure. It is not necessary to take these up here in minute details as they are fully described in various recently published manuals of military hygiene or in War Department circulars.* The idea is merely to give a broad and comprehensive view of the fundamental principles of the subject, to emphasize its importance, and to try to induce the lately appointed medical officer to familiarize himself with the plan of campaign necessary in controlling the incidence of the intestinal type of infectious diseases. We have now learned how to prevent and have indeed practically eliminated the typhoid group of fevers. If we could control dysentery as successfully, the biggest outstanding problem in military hygiene might be considered as satisfactorily solved. It may be noted here that in accomplishing the prevention of bacillary and amebic dysentery we would at the same time control the simple or so-called catarrhal dysenteries and the ordinary camp diarrhea, diseases which, while not in themselves dangerous to life, yet serve to largely bulk the sick reports at times, and thus interfere seriously with military efficiency.

As in all infectious diseases, we should endeavor to prevent the operation of the usual predisposing causes, which act by lowering the vital resistance of the individual. We should avoid, so far as possible, fatigue, exposure to cold and dampness, overcrowding, indulgence in alcohol, in fact, general bad personal hygiene of any kind. It is possible, too, that mechanical or chemical irritation of the mucous membrane of the large intestine from unripe or decomposing fruit, or indigestible food, or food in which the germs of putrefaction have begun to work, may predispose to dysenteric attacks.

The dysentery class of diseases, to note their fundamental epidemiology, is spread through the bowel passages of a patient or carrier, infecting directly or indirectly, water and food, or the hands, clothing or bedding, and being thence taken into the intestinal canal of another individual through the mouth.

Given a reasonably vigorous and healthy personnel, what general measures should we then adopt in an antidysentery campaign?

1. We *isolate* patients. We disinfect their stools by 5 per cent. liquor cresolis compositus in equal parts, mixed and left to stand for an hour. We sterilize infected clothing and bed clothes, pre-

ferably by heat where steam sterilizers are available; if not by immersing the articles in a 2½ per cent. cresol solution.

2. It goes without saying that we should look most carefully after the *water supply*. The new development of motor laboratories marks a decided advance in this connection in the field. The examination of water is usually limited to estimation of the total bacterial count (on agar) and to obtaining figures for the least amounts of the water samples containing lactose fractors, (McConkey's bile-salt-lactose-litmus broth). These simple determinations have been found to serve in practice as a satisfactory means of differentiating unsafe waters. Any water not tested or not responding satisfactorily to these simple tests must be sterilized before use. The method of purification by boiling, of course, is always sufficient when practicable. When this plan is not available, the method most generally suitable has been found to be chemical sterilization, and the reagent now most used is bleaching-powder (calcium chloro-hypochlorite), using one part per million of available chlorine. This strength requires about one gram of the salt for the Lyster water bag of our Army, or two grams for the English Army water-cart. Samples of the chemical should be titrated from time to time to check the loss of strength to which it is liable (by Penot's arsenious acid method or by the thiosulphate test).² Filtration methods are unreliable in the field.

3. The careful supervision of the methods of *food supply* is a prime necessity in antidysentery work. Milk supplies should be boiled. Screening of food and of cooking and eating utensils against flies is naturally of great importance. Fresh vegetables are a great source of danger, especially in tropical countries where the native and Chinese truck-gardeners use, for fertilizing, the method of sprinkling liquid sewage and excrement over the growing vegetables. We found at Corregidor in the Philippines that the prohibition of the importation of green vegetables was followed by a drop almost to zero in the dysentery rate which had previously been large. The most important procedure of all in relation to the soldier's food supply is the elimination of "carriers" from among all having to do with the cooking and serving of food, and this measure seems to have special importance in relation to dysentery. The chief factor in the spread of the amebic form of the disease seems to be encysted amebæ in the stools of convalescents and healthy carriers. It is evident then that it is extremely dangerous for these men to handle food. The inculcation of the habit among soldiers of washing the hands before eating is a measure of priceless value in preventing the spread of dysentery, probably more important than in any other disease except cholera.

4. In fighting all the infectious diseases of intestinal nature, it is an absolute necessity that we pay the most careful attention to methods of disposal of *excreta and wastes*.

(1) For the satisfactory handling of human excreta, we usually adopt for temporary camps the English shallow straddle sink method, preferably with the Patterson modification of wooden covers; for semi-permanent camps, we use the deep trench latrine pit in connection with the Havard type of

*See Havard's Manual of Military Hygiene, Third Edition, 1917; Lelan's Sanitation in War, 1917; Stitt's Diagnostics & Treatment of Tropical Diseases, 1917.

box with covered seats. The pits are burned out daily with straw and oil or sprayed with lamp black in kerosene. Lucas of the New York National Guard has developed the Patterson cover idea so as to make it apply to the pit method. A flat cover is made to fit closely over the top of the trench and holes with self-closing lids are placed conveniently along the length of the cover.³ This device is probably, at least with reference to dysentery, an improvement on the boxed seat, as it is less liable to fouling and can be more easily cleaned. All these details are of course adopted for the purpose of fly-proofing and preventing the breeding of flies. Special methods of handling urine are less important in dysentery than in typhoid owing to the fact that in the former neither the amebæ nor the bacilli are excreted in the urine. However, owing to the frequent stools in dysentery and the mucous consistency of the discharges, contamination of the hands and of the seats of the latrines is much more likely than in other intestinal diseases. We should therefore wash off the seats frequently with 5 per cent. cresol solution and keep the same solution handy, requiring the soldiers to wash their hands with it after using the sink.

(2) Kitchen wastes and the general waste of the camps can only be handled satisfactorily in one way, according to modern ideas, and that is by incineration. The principal thing here, of course, is the warfare against flies. If we have mechanical crematories, well and good; if not we extemporize rock pile kitchen and camp incinerators, usually according to the Straub models⁴ which have given good service in many camps, even divisional in size.

(3) The proper handling of horse manure is naturally of importance in any situation that requires the control of fly-breeding. Careful daily removal of manure from and cleaning of the picket lines is essential, as also the burning over of the surface of the ground concerned. The refuse itself must be carted away a sufficient distance or preferably dried and burned in some one of the extemporized incinerators that have been invented for this purpose.

The question of the transfer of dysentery by dust has not been conclusively settled. If by the methods above described, soil infection can be adequately prevented, dust will, however, not be dangerous in this connection.

Taking up now the very important problem of the specific measures that may be made available against dysentery, we shall consider separately the amebic and the bacillary forms.

1. Since amebic dysentery is no doubt largely spread by cysts in the bowel passages of "carriers," the specific treatment with ipecac of the latter, especially convalescents and those carriers having to do with the preparation of food, such as cooks and mess orderlies, is rational.

For the abolition of the cysts in the stools, not less than 12 grains of the emetine salt, administered in one grain doses daily, is necessary.

A late improvement is the substitution of emetine bismuth iodide for the formerly used hydrochloride salt. This is given in large doses, *i.e.* not less than a total of 36 to 40 grains in daily doses of three to four grains. Very successful results have been obtained by the use of this method. The dif-

ficult thing, of course, is the locating of the carriers.

2. Unfortunately it cannot be said that the present status of the question of the specific prophylaxis of *bacillary* dysentery is entirely satisfactory. There have been certain results, it is true, from the experimental work that has been done along these lines, but they are not yet in the practical shape that we would like to have them for use in the Army. However, it seems to me that the situation is at least encouraging, though some authorities are inclined to be pessimistic as to the future of the problem.

Shiga in Japan in 1898-1900 vaccinated with dead bacilli, plus specific serum, 10,000 inhabitants of a district where the disease was prevailing, and while the incidence was apparently not lowered, the mortality was reduced to about one-third of what it had formerly been.

Castellani in 1913 reported "fairly good results" from the use of dead bacilli, followed a week later by live non-virulent germs. He now uses a polyvalent vaccine, a carbolized emulsion (others prefer cresol) of least-virulent strains prepared from agar cultures without heating. He avoids the use of broth in the preparation of cultures on account of the severe local and general reactions that follow the use of vaccine made in that way. Indeed this severity of the reaction—this violent "kick" as one may say—has been one of the principal stumbling blocks in the way of successful experimentation.

There have been some rather promising results obtained in the last few years. In Kanagawa Ken in Japan in 1908, 3253 persons were vaccinated against dysentery. Of these thirteen or 0.4 per cent. contracted the disease with no deaths. Of 632 individuals not vaccinated, eighty-eight or 13.92 per cent. did contract it with twenty-one deaths.⁵ These figures are not large enough to prove the case conclusively, but are nevertheless highly significant.

There was an epidemic on the borders of Galicia in 1915 in which several hundred persons were inoculated with a polyvalent vaccine. The epidemic was apparently stopped in this way.

F. Noc in Cochín China, in 1915 claimed to use immunization with antidysentery vaccine, plus serum, with good results. Busson in Germany in the same year found in animal experimentation that the best results, including a lessening of the severity in the reaction, came from the use of the dysentery toxin plus the antitoxin, the latter being used in a quantity insufficient for the complete neutralization of the toxin.

In a local epidemic of bacillary dysentery in the German army, in 1916, 2000 inoculations were made, and it is said that no further cases occurred in the infected district.

In Hawaii in 1916 an epidemic in children was completely aborted by inoculation of vaccine in the healthy (the "Y" organism isolated from the stools).

Gibson of the Royal Army Medical Corps thinks there is a good chance of the success of the inoculations in the army. They were being tried in the field in France last summer. Reports of the results are not yet obtainable. He used a trivalent vaccine of the Shiga, Flexner, and "Y" types.

The short immunity so far obtainable (only a few months at the best) is one of the things that has discouraged the investigators. It is to be hoped that some method may be found to extend this period materially. In any event even that short time, if really obtainable, might under army conditions be found to be of the utmost importance. The newly discovered methods of using oil in the injections will no doubt greatly reduce the severity of the reaction and thus tend to encourage experimentation on a large scale among the troops.* The desideratum is of such vital importance to the well-being and the future of armies, that it seems to me it merits much greater attention and perseverance than has heretofore been given to it by laboratory investigators.

A valuable hint and a hope that the problem may still be solved has very recently been given by M. Roux.⁶ One of his collaborators found that the disappearance of the dysentery bacillus from the stools of convalescents coincided with the appearance of an invisible antagonistic microbe. A bouillon culture after 18 hours at 37° C. was passed through a Chamberland filter, L2. The filtrate was found to have the property of arresting cultures of the Shiga bacillus, causing death and finally lysis (on agar plates, circles where the culture is null show disappearance in those places of the dysentery bacillus). The antagonism is apparently not inherent in the invisible microbe but acquired by symbiosis. This microbe has no pathological action on experimental animals. Rabbits are immunized by the culture of Shiga which has undergone lysis, that is by the culture of the antimicrobe, against a dose of toxin killing controls in five days. Roux calls this a heterologous antimicrobial immunity. While this discovery may not prove to have an important bearing on the solution of our problem, it seems to indicate that there is no reason why we should become discouraged. It is probable that we have not yet learned everything about the complicated question of immunity, even in its more practical aspects. Let us endeavor to stimulate our laboratory associates to work out a practicable method of anti-dysentery inoculation. One who could do this would indeed accomplish more lasting good than a hundred doctors in the trenches.

*Whitmore at the Army Medical School has recently prepared an oil-suspended triple dysentery vaccine, containing the Shiga, Flexner, and "Y" types of bacilli. Results so far have been quite encouraging, both as to lack of toxicity and for immunity response.

Alcohol and Blood Pressure.—Lian examined 150 soldiers aged 42-43 years. Of 16 sober men (who did not exceed a liter of wine daily) but one showed hypertension; of 13 moderate drinkers (1 to 1.5 liters of wine), one also showed hypertension; of 6 ordinary drinkers (2 to 2.5 liters of wine plus bracers of spirits), one was hypotensive. Of heavy spirit drinkers one in four showed hypertension.—*Archives Médicales Belges*.

A CASE OF PATENT URACHUS, WITH ABSCCESS, COMPLICATING AN HYPERTROPHIED PROSTATE.

By W. TRAVIS GIBB, M.D., F.A.C.S.,

NEW YORK.

VISITING SURGEON, CENTRAL AND NEUROLOGICAL HOSPITAL.

ALTHOUGH surgeons and anatomists for several hundred years have recognized the existence of urachal abnormalities, indicating the patency of that structure in one form or another, the occurrence of these cases, especially complete patency in subjects well advanced in years, is sufficiently rare to justify the report of a case recently operated upon in the Central and Neurological Hospital.

In very early fetal life the urachus develops from the allantois and forms a canal from the bladder to and sometimes through the umbilicus. It is normally patent at the second month of uterogestation, but later on in fetal development the canal should become obliterated and its walls consolidated to form a more or less distinct fibrous cord, which becomes the median suspensory ligament of the bladder in its lower part, and its upper portion is usually imbedded beneath the peritoneal layer of the anterior abdominal wall. If, after birth, this cord should continue to remain pervious to the slightest degree, permitting communication with the bladder, it becomes possible for a urachal sinus or cyst to develop, especially if any interference with the expulsive function of the bladder should arise from an imperforate urethra or a tight prepuce.

Where the urachus remains more or less patent in adult life, the canal may open into the bladder with the distal end closed; the distal end may remain open, and communicate with the umbilicus with the bladder end closed; in another type, both the proximal and distal ends may be closed, leaving a fusiform cyst between; the most uncommon type in adult life is where the entire urachal tract remains patent. Beadlike or fusiform cysts of the urachus of varying sizes, but usually small, may be encountered in median laparotomy incisions where the patient and the surgeon were previously unaware of the existence of such a condition.

The largest number of urachal abnormalities is encountered in the newborn, where urinary fistulæ at the umbilicus are occasionally found after the cord has dropped off, but if there is no real obstruction to the bladder outlet from an imperforate urethra, or an abnormally tight prepuce, these urachal fistulæ will gradually close and disappear. Ordinary urachal abnormalities, such as blind fistulæ, cysts, etc., cause little or no discomfort unless they become infected and produce abscesses of the anterior abdominal wall, which may open into the bladder or through the umbilicus. A blind urachal fistula opening into the bladder may be the site of the formation of a urinary calculus, and give rise to obscure bladder symptoms.

Urachal cysts are usually small and unimportant, but occasionally cysts of this type have grown to enormous size. One reported by the Mayo brothers was the size of a uterus at term, and another mentioned by an earlier writer weighed over 100 pounds. These very large urachal cysts are so rare that they are usually diagnosed as ovarian, and only differentiated at operation.

The types of pathological urachus which are of the greatest interest to the surgeon are those which produce symptoms necessitating operative interference for their relief, but a patient may go through life with a pathological condition of the most interesting kind involving his urachus and never be aware of the fact unless some obstruction to the normal bladder outflow, due to prostatic hypertrophy, impervious urethral stricture, impacted calculus, or obstructing new growths, produce such an amount of bladder distention that the urine, following the line of least resistance in seeking another outlet, enters the patent urachus and produces symptoms calling attention to the condition. Complete urachal fistulæ due to hypertrophy of the prostate in the aged is one of the most infrequent types of urachal abnormality, and but few cases have been recorded.

Urachal cysts are more common in women, but completely patent urachal sinuses occur more often in men, owing to the greater frequency of urethral obstruction among them. Many of these conditions may exist during the life of the patient, producing no symptoms, and may not be discovered unless encountered in the course of an operation or at autopsy.

The following case was especially interesting on account of the man's age, the duration of his disability, the complete restoration of bladder function, and the closure of the urachal sinus:

M. T., aged seventy-four years, was admitted to the Central and Neurological Hospital, December 5, 1916, suffering from general abdominal pain and discomfort, complete cessation of urethral urination and passing all his urine through the umbilicus. His family history was good. Personally he had always been in good health. Had typhoid fever when thirty years of age. For many years he had been in the habit of drinking eight or ten glasses of beer and several glasses of whiskey daily. His heart, lungs, and gastrointestinal organs were normal, but he had lost fifteen pounds in weight during the past year.

Three years ago he began to suffer from dull pains in his hypogastrium, with distended bladder and the gradual cessation of the free flow of urine from his urethra. The flow gradually became dribbling in character, and several months before entering the hospital urine began to exude from his umbilicus, and as the urethral flow diminished the flow from his umbilicus increased, until finally about a month before his admission his urethral flow ceased entirely and he passed all of his urine through his umbilicus.

The patient was short and stout, anemic, with small flabby muscles and atheromatous arteries. His abdomen was distended, his umbilicus protruded and from it flowed constantly a cloudy fluid with a urinous odor. A rounded mass, dull on percussion and tender to pressure, was found in the hypogastric region just above the symphysis. His prostate was very much enlarged, especially the middle lobe, and a small sound could be passed with difficulty into his bladder. His urine drawn by catheter contained pus in considerable quantities and a few hyaline casts. The fluid from his umbilicus contained a larger admixture of pus than that obtained by catheter from his bladder. Methylene blue appeared in his urine twenty minutes after the tablet had been swallowed. His blood pressure was low for his age; systolic 130 mm., diastolic 60 mm. Differential blood count was practically normal.

He was treated expectantly for some time with tonics and bladder irrigations until his cystitis had greatly improved and his general health was as good as could be expected, when suprapubic prostatectomy was resorted to early in February, 1917.

Under general anesthesia the bladder was irrigated and distended with about twenty ounces of warm boric acid solution, and after the usual preparation an in-

cision 8 cm. long was made in the median line, just above the pubes. On dividing the fascia, rectus and pyramidalis muscles a considerable amount of indurated tissue and adhesions were encountered over the bladder, and on going a little deeper an abscess cavity was entered near the apex of the incision. This was evidently the distended urachus and contained about 60 c.c. of pus having a urinous odor. This abscess was evacuated and carefully wiped out, and on dissecting deeper over the bladder in the median line, in the lower angle of the wound, an irregular diverticulum of the peritoneum was entered, but the rent was quickly sewed up.

The bladder wall was very thick and adherent to the surrounding structures, and there was a marked inflammatory exudate on its anterior surface. The bladder was more or less fixed and it was impossible to push the peritoneum upward from its anterior surface. An incision about 4 cm. long was made into the bladder, as near the fundus as possible, and through this incision the enlarged prostate was very easily enucleated, lobe by lobe, aided by an assistant's finger in the rectum. A general oozing from the bed of the prostate persisted and was controlled by hot packs. A large self-retaining drainage tube was fixed into the bladder and held by several layers of purse-string sutures in the bladder walls and fascia. The wound was closed with tier sutures in the muscles, fascia, fat, and skin. A self-retaining urethral catheter was left *in situ* for twenty-four hours.

A continuous drainage of urine was maintained, the bladder was irrigated with warm boric acid solution three times daily, and the patient made an uneventful recovery. As he continued to pass all his urine through the upper drainage tube, after a reasonable time this was clamped off in an effort to make him pass urine naturally through his urethra, with very gratifying results. On the twelfth day after the operation the suprapubic tube was removed, and the edges of the wound brought together with adhesive strips. The suprapubic wound closed promptly without suppuration. There was no leakage of urine through the umbilicus after the operation.

The pathological report of the specimen removed showed hypertrophy of the prostate of the interstitial type.

The patient has been passing his urine normally at normal intervals, and has returned to his work.

42 WEST SEVENTY-FIFTH STREET.

TRAINING THE MYOCARDIUM.*

By HUBERT SCHOONMAKER, M.D.,

CLIFTON SPRINGS, N. Y.

IN the treatment of heart disease first place should be given the myocardium. Its efficiency should be determined at the outset. The significance of valvular defects is no less than when until recently text-book authors made them the essential factors in heart pathology. It is highly important that valvular defects be recognized and differentiated, for the treatment of mitral diseases may be quite different from that of aortic disease, and that of mitral stenosis quite different from that of mitral insufficiency, yet, no matter what the lesion the efficiency of the heart is in direct ratio to the strength of the myocardium.

Of the five special functions of the heart as demonstrated by Gaskell, namely that of stimulus production, of excitability, of conductivity, of contractility, and of tonicity, the last two are of particular interest in relation to our subject. MacKenzie states that the function of contractility is

*Read at the Annual Meeting Wayne County Medical Society, Lyons, New York, December 11, 1917.

the power to contract when stimulated, and the function of tonicity the power to retain a certain amount of contraction when the muscle is inactive. An abstract example of the relative loss of function of contractility is the heart at the close of a typical run of typhoid fever; of the function of tonicity, the dilated heart following physical overstrain. It is obvious that a disturbance of either function tends to involve the other, nevertheless our conception of the needs of an imperfectly functioning myocardium is the clearer, if in our analyses we consider them as distinct.

The underlying principle in training the myocardium is essentially the same as that in training the voluntary muscles, namely, alternate exercise and rest. Exercise should stop short of exhaustion either immediate or remote. Rest should provide time only for recuperation and reaction. Either over-done is fatal to results.

To determine the reserve force of the heart it is essential to observe closely subjective symptoms and changes in rate and character of pulse and in systolic, diastolic, and pulse pressure under exercise or change of position, as from the reclining to the upright. Any scheme for working this out is better than none. None is infallible. As a routine we note pulse, systolic, diastolic, and pulse pressure, first with patient reclining and fully relaxed. The reclining position should be always the same in relation to a given patient for the reason that there is a difference of from 5 to 20 mm. Hg. between the supine and the lateral positions, the pressure in the supine being the greater. This difference is so constant that for the purpose of estimating myocardial reserve we believe it best to make use of the lateral reclining position. If the patient is ambulatory, we then have him walk at ordinary speed, 100 feet, then read the manometer and take the pulse as before with him standing. After resting, sitting for a minute, we have him walk down and up a flight of stairs without hurrying, and read as before. We then have him lie down for the purpose of observing how long it takes the pulse to return to the rate of the first test. These findings are recorded side by side and interpreted in terms of myocardial efficiency. In a normal heart there should be a pulse increase of from 10 to 15 in the second over the first test and from 10 to 20 in the third over the first; with, upon resting, a return to the rate of the first in one minute or less. There should be an increase in systolic pressure and in pulse pressure of from 10 to 15 mm. Hg. in the second over the first, and of 10 to 20 or more in the third over the first. At the same time there should be no undue increase in respiratory rate, no dyspnea nor chest discomfort. The color should be somewhat heightened and the pulse fuller. Any departure from the normal may be interpreted in terms of myocardial efficiency, *e.g.*:

	Pulse	Systolic Pressure	Diastolic Pressure	Pulse Pressure
Test 1.....	80	120	80	40
Test 2.....	90	125	80	45
Test 3.....	100	135	75	50

Return of pulse rate to that of Test 1, one-half minute. This is a normal response.
Take another case with the same response in Test 1:

	Pulse	Systolic Pressure	Diastolic Pressure	Pulse Pressure
Test 1.....	80	120	80	40
Test 2.....	100	120	90	30
Test 3.....	120	110	90	20

Return of pulse rate, 2 minutes. In the second case it is obvious that under light exercise and change from the reclining to the standing position the cardiovascular system, and probably the myocardium in particular, is incompetent, while under the third test (walking up a stairs) incompetency is apparent. In the two cases the readings in Test 1 are identical. The blood pressure picture based upon the three tests in the first case suggests normal myocardial function, while in the second case it suggests markedly deficient function.

Once one has determined the myocardial reserve, the heart at stated intervals should be made to utilize a part of the same. Static force should be converted into dynamic. Every school boy knows what happens to the biceps when so treated; so also the myocardium. Exercise of function begets function, so long as the reserve is not exhausted. In bed cases myocardial training should be essentially of the passive order, but may be both passive and active. In ambulatory cases it should be essentially active, but may be both active and passive. By passive training we mean the use of any means other than contractions of the voluntary muscles. By active training we mean the use of the voluntary muscles. Passive training makes use of drugs of the digitalis group, the therapeutic action of which is to stimulate the myocardium to utilize its reserve, and to increase further that reserve by lengthening the heart's diastole. It makes use of the carbonated saline or Nauheim bath, which tends to raise the blood pressure sufficient to increase moderately the work of the heart while under treatment, to improve capillary circulation, and to stimulate the sympathetic system. It makes use of Swedish or other passive exercises which quicken the blood flow and indirectly improve the cardiovascular tone. It makes use of massage which flushes the blood and lymph channels of the deep tissues as well as the superficial.

Active training makes use of resistance exercises whereby individual groups of muscles are made to labor, little or much according to the judgment of the operator. It makes use of inhalation and exhalation, somewhat beyond that of the physiological need, at stated intervals and for a prescribed time. It makes use of walking or any sport in which walking is the chief physical element.

To elaborate: According to Cushny, digitalis in therapeutic doses stimulates the muscle cells of the heart (augments the function of excitability) and slows the heart by stimulating the inhibitory centers in the medulla; transmission being by the vagus. This dual action leads to increased response to stimuli, as may be seen in the occurrence of extra systoles, and to slowing of the heart with resulting increase in length of diastole and in force of systole.

In the carbonated saline bath the essential factor is cold. Cold causes contraction of the arterioles, elevation of blood pressure, deeper inspira-

tion and expiration, and consequently extra heart work. The CO₂ saline mixture makes possible a cold tub bath without discomfort or shock because the ingredients stimulate the cutaneous circulation and retard heat radiation. By this physiological complex of increased blood pressure dilated capillaries, stimulated sensory and vasomotor nerves, and augmented respiratory function, the heart is made to draw upon its reserve, while at the same time the peripheral field is freer because of a better cutaneous and pulmonary circulation.

Passive exercises consist of movements of the joints in all directions without any effort on the part of the patient. The system is of use at the beginning of myocardial training when reserve is very small and the individual physically weak. The exercises can be given by a nurse or a trusty member of the family, but at first this should be under the observation of the attending physician, in order that a safe estimate of myocardial reserve may be made.

Resistance exercises are embodied in a system, a description of which can be found in special works and in some text-books on general medicine. The essential element in the system is exercise of single groups of muscles against resistance, by either a second person or oneself; for instance, with the patient standing, the forearm is slowly flexed upon the arm while the attendant resists the effort by pressing in the opposite direction, the palm of his hand being against that of the patient's. The arm is then extended in like manner. This procedure is repeated four to six times. After a few minutes' rest a second group of muscles is treated and so on; or the patient may resist his own effort by contracting the opposing muscles. The number of exercises at each séance and the degree of resistance should be determined by observation of symptoms and myocardial reaction. No treatment should exhaust the myocardial reserve.

Massage stimulates the whole circulatory tree by increasing the circulation within the vessels and lymph channels. It is applicable to both bed and ambulatory cases and in degree may be given from the lightest possible manipulation of a single member for a few minutes to a deep full body treatment lasting an hour. Each treatment should draw upon myocardial reserve, but again not to exhaustion of the same. It is to be remembered that much harm as well as good may be done the heart by massage. The operator should understand the needs of the case at the outset.

In ambulatory cases there is no single agent more potent than walking. This exercise should be graded according to the needs of the case, remembering that there is no agent so fraught with harm. The prescription may be definite as to time, grade, and speed, but a failure as to results; for the act is essentially volitional and, pathologically speaking, individuals are seldom good judges of their own needs. The essentials in myocardial training by walking are use of the voluntary muscles, especially those of legs, back, and chest, an increased exchange of the gases of the lungs, and exercise of the myocardium. To be effectual, walking must involve active contraction of the

leg muscles. The weight of the body should be raised on the ball of the foot and toes with each step. At the same time the body should be erect, chin in, and chest elevated, in order that the heart may have free play in the chest and that full inhalation and exhalation may be possible. Unless the patient is instructed in the matter of walking properly he may saunter in a listless manner with relaxed muscles the prescribed time, with resulting harm rather than benefit. He should be made to understand that in walking he is taking a treatment for his heart. He should be informed of the gross physiology of the heart and the object of the exercise. To avoid the danger of overtax, we have adhered to a rule that seldom fails. After estimating, approximately, the myocardial reserve the patient is instructed to walk on the level in the manner noted and in the open air, if not contraindicated, 5 minutes every two or four hours throughout the day, according to the case. The second day the time is increased to 6 minutes, and so on until 15 minutes is reached, the goal being an hour's walk in 4 to 8 periods daily. Each period must be followed by rest, reclining, and fully relaxed from one-half hour to the whole interval. In some cases it is best that the patient spend the whole day in alternate exercise and absolute rest. This plan meets the two essentials in the development of a muscle, namely, alternate exercise and rest of that muscle; its benefits are multiple in that it develops at the same time the heart and the skeletal muscles and increases metabolism. Once myocardial reserve is sufficient to warrant it, a light grade is added. When the myocardium is sufficient for this, heavier grades are added until hill-climbing is easy. During this training the patient is learning his physical capacity, a most important matter in relation to his future.

In this cursory review of methods of physical training which are adapted to the rebuilding of a weak myocardium, I have attempted to say that increase of storage energy is best obtained by systematized use of existing energy to the point of development of function; that the same general rules apply to training the myocardium as to training voluntary muscles; that intelligent co-operation on the part of the patient, including a sufficient knowledge of the physiology of the heart and the object to be obtained, is important; that systems of training the myocardium, both passive and active, may well be utilized, either separately or in combination, in the treatment of almost all weak hearts; that graded exercise by walking is a potent method in ambulatory cases; and that a combination of systems, as, for instance, exercise by walking alternating with rest, carbonated-saline baths, massage, and digitalis, which combination stimulates to better function the whole circulatory tree from the heart to capillaries, lymphatics, and veins, is in many ambulatory cases more potent than single remedies.

Bright's Disease and Tuberculosis.—Nathan, who has seen cases of this coincidence, states that hypertension is naturally a bad element for the consumptive, while edema is prone to have a pulmonary localization.—*La Presse Médicale*.

A STUDY OF GENITAL AND PROGENITAL PAPILLOMATA AND EXCRESCENCES.

BY NOAH E. ARONSTAM, M.D.,

DETROIT, MICHIGAN.

THE growths noted in the above title, which stands in lieu of the timeworn and obsolete designation "Venereal Warts," have received but little attention heretofore in medical literature. Some authors merely suggest their existence in a cursory manner, and those who consider them somewhat in detail fail to view them from a scientific standpoint, intimating solely the clinical aspect of these lesions and paying little heed to their morbid anatomy and etiology. The writer has reason to believe that they are of much interest, not alone to the genito-urinary surgeon, but also to the general practitioner. They are not infrequently the first messengers of some affection in distant organs or tissues of the body, permitting by their presence a number of valuable inferences to be drawn, serving as important diagnostic indices for certain abnormal states of the organism, and aiding greatly rational therapeutic efforts in overcoming concomitant conditions, of which they are only expressions or symptoms.

Our first attention will be directed to the study of the genital and progenital papillomata; subsequently other excrescences will be discussed in order of their frequency.

The former may be divided, for convenience of study, into the following classification: (a) papilloma simplex; (b) papilloma acuminatum; (c) papilloma gigantum; (d) papilloma latum; (e) papilloma molle; (f) papilloma maligniforme, and (g) a type sui generis—papilloma urethrale.

Following the reader will find an elucidation of each variety separately, giving briefly its pathology, enumerating the etiological factors leading to its inception, outlining the methods of treatment now in vogue, and stating the prognosis in relation to other morbid states of the economy.

Papilloma Simplex.—This is the form designated in older writings as "venereal wart." It is of common occurrence, especially during the periods of puberty and adolescence. Males are more frequently affected than females, particularly those of a weak and unstable nervous constitution. Its location is in the integument of the genito-urinary tract and its adnexa; the sulcus glandis in the male and labia majora in the female being favorite sites. It denotes an intensification of anabolism, an exaggeration of tissue construction met with during the period above mentioned, wherein the anabolic activity far exceeds catabolic counteraction. This constitutes a most important predisposing etiological factor. Uncleanliness of the genitalia and the contiguous parts, a tight prepuce, the presence of the smegma bacillus, and occasionally some forms of helminthiasis are responsible for its production. Hyperactivity of the sebaceous glands in the preputial sulcus is another potent cause. Excesses in venery, ungratified sexual desire, and the irritation attendant upon masturbation are likewise apt to induce this affection. By reason of the influence which the vasomotor nervous system exercises in the period of extreme growth and functional activity, as during pubescence, the nervous system is

likely to be burdened with the brunt of the process, which is partly characterized by an augmentation or rather perversion of function of the nerves regulating circulation and nutrition. Local vasomotor paralysis ensues, eventuating in dilatation of the capillaries of the layers of the corium and thus favoring transudation within the adjoining structures, factors instrumental in the production of the simple genital papillomata. The morbid anatomy of this form of wart is comprised in the foregoing explanation of the agency of the vasomotor nervous apparatus in the causation of these lesions. In short, the entire process may be regarded as a trophoneurosis. Simple papillomata manifest no subjective symptoms, being *indifferent* throughout. Their color varies from a dirty gray to a yellowish brown or black, with numerous intermediary shades.

The treatment of papilloma simplex consists in the removal of the causes productive of this lesion. Of course, we cannot curtail the physiological period of adolescence, but we can materially aid in removing the lesions by topical applications. Cleanliness is not only curative in the majority of cases, but it is also a valuable prophylactic agent. Bathing the genitalia and adnexa with a weak solution of boric acid, as hot as it can be borne, acts very favorably upon the growths. In no instance should heroic measures be employed. Cauterization should be avoided by all means, and resorted to only when all other measures fail. After the papillomata have been washed with the above mentioned solution, they may be dusted with a drying powder of the following composition:

R Aristolis 2.0
Bismuthi subnitratris 8.0
Magnesii silicatis 20.0

M. et fiat pulvis; or the following solution may be applied:

R Acidi tannici 4.0
Adrenalin solution 1-1000. 2.0
Collodii flexilis, or
Tr. benzoini comp. q.s. ad. 15.0

Sig. Apply with a camel's hair brush every second day.

In case they seem rebellious to the above procedure, more potent remedies may be tried, namely:

R Ac. salicylici 4.0
Sol. adrenalin 1-1000..... 2.0
Resorcini 1.5
Collodii Flexile 8.0

Sig. Apply with a camel's hair brush once or twice a week.

After three or four applications, the warts drop off, leaving a normal or slightly reddened base underneath. If pain is experienced during the exhibition of the above applications, a few grains of the hydrochlorate of cocaine may advantageously be combined with the foregoing formulæ. As already intimated, the use of escharotics or highly irritating agents must be refrained from, lest an ugly ulcer result, which may prove very obstinate and resist treatment. Thuja occidentalis, which has been recommended by some authors, has proven ineffectual in my hands in this form of papilloma. Magnesium sulphate in ten grain doses three times a day has in few cases acted admirably in eradicating these lesions without having recourse to any other form of medication. When cleanliness is per-

severed in, the simple papilloma is likely to disappear without the aid of medical agents. Small doses of zinc phosphide tentatively administered have a very pronounced effect upon those growths, the result of perverted nerve activity, and are mainly indicated in nervous individuals. *Tinctura cocci cacti* in ten minim doses is warmly recommended by some authorities. The administration of a mixed staphylococcus vaccine has proven efficacious in a number of instances.

Papilloma Acuminatum.—This is a variety of papilloma peculiar to the genital region only. It is an essential genital lesion. In the male, it is found on the mucous or cutaneous surface of the prepuce and its sulcus. Occasionally entire ridges may be seen to extend in a perpendicular direction on the dorsal surface of the penis. The scrotum participates in the process, and may be studded with a number of these growths. In the female, the posterior commissure and the fourchette may be the seat of this particular form of papilloma. The labia majora may likewise be involved, less so the labia minora, which are the habitat of another variety of excrescence, namely, the *papilloma molle*. The individual lesions resemble ordinary warts, but are more pointed than the latter, acuminated, very slender, considerably indurated, and their surfaces are extremely rough and corrugated. They seldom exceed one-eighth of an inch in depth, and are more or less sensitive. They are of a muddy, gray, or brownish-black coloration. Their cause is to be sought in some abnormal condition of the genital organs. Gonorrheal erosions, ulcerations, both luetic and chancroidal, or those due to pre-existing herpetic eruptions, furnish an adequate soil for the development of this variety of wart. A number of cutaneous diseases, as scrotal eczema, lichen, keratosis pilaris, and the syphilodermata affecting the prepuce and dorsal surface of the penis and scrotum in the male, and the posterior commissure and labia in the female, may bring out this dermatosis. Urethral inflammations, specific or otherwise, and leucorrhœal discharges, diseases of the uterine mucosa, giving rise to irritating secretions, may likewise produce it. Vesical calculi have been known to cause acuminated papillomata, reflexly. A redundant and constricted prepuce, increased secretion of smegma, and the presence of round worms are apt to cause it. Adolescence and middle life are the ages mostly attacked. The morbid anatomy of this variety of papilloma is identical with that of papilloma simplex, and hence need not be repeated.

The treatment consists in the removal of the causative factor and the institution of scrupulous cleanliness. The local applications recommended for the former variety are equally applicable to this condition. Besides these, the cautious application of chromic acid or the use of a strong solution of silver nitrate will eventually eradicate the malady. The area adjoining the wart, however, must be well protected, lest the caustic come in contact with the healthy tissue and work havoc on it. The electrocautery may at times be necessary to destroy these growths, but it is a painful method of procedure, and should be resorted to only after all the milder remedies fail. Ablation by the knife is much better than the use of escharotics, after which the raw

surface may be touched with a mild astringent and stimulating agent, as tincture of iodine or a solution of silver nitrate, 10 grains to the ounce. The tincture of thuja occidentalis acts well in this particular form, and should be given in ascending doses. If there is a syphilitic basis underlying this form of papillomata, specific treatment must be instituted without delay.

Papilloma Giganticum.—This variety of papilloma invades most often the ischio-rectal space, perineum, the inner aspect of the thighs, and the genitalia in both sexes, and may assume enormous dimensions, reaching at times the size of a hen's egg. The anal region is a favorite location of papilloma giganticum, which may completely encircle it. It gives rise to subjective disturbances, as smarting, burning, and itching, and thus occasions a great deal of suffering and discomfort.

The etiology of this form of papilloma is rather obscure; venereal causes do not seem to influence it much, for very few individuals, the subjects of papilloma giganticum, are the subjects of venereal affections. Rectal diseases, as hemorrhoids, fistula in ano, fissures, and neoplasms of the rectal mucosa, are credited with its causation. Many nervous disorders, as hysteria, neurasthenia, general paresis, tabes dorsalis, and disturbances of the vasomotor nervous apparatus are known to be accompanied by papillomatous excrescences in the regions above mentioned. Vaginal affections and disorders of the uterus are etiological factors, known to have inaugurated this form of wart. Its pathology may be summed up in the following short description: The papillæ of the corium are enormously enlarged and the rete mucosum is filled with large pigment granules of an abnormal type; there is also a hyperplasia of the various layers of the stratum corneum. Their color varies from yellowish gray to that of a dirty brown; some assume a greenish hue.

The treatment consists in the extirpation of these growths by the knife. Chemical escharotics and the electrocautery are of no avail in this form. Concomitant affections must be remedied, pathological conditions within the rectum removed, and uterine abnormalities corrected. The higher nerve stimulants may be tried, if there are coexisting nerve lesions. Arsenic in the form of Fowler's solution is indicated under these circumstances, or the intramuscular injections of sodium cacodylate acts very beneficially upon the local diseases as well, by virtue of its epithelial predilection.

Papilloma latum and *papilloma molle* may be considered collectively, as they constitute really various grades of the same affection, differing only in degree, not in kind. They are of a soft consistency, and their favorite location is the perineum, anus, and the integument of the penis in the male, the labia majora and minora and the posterior commissure in the female. The gluteal fold and ischio-rectal space may likewise be the seat of this form of papilloma. They may also be occasionally observed in remote places, as in the hypogastric region, the lower third of the inner surface of the thighs, and the popliteal space. The papillomata lata are apt to assume considerable proportions. In color they suggest a pearly hue, bordering on grayish-blue. They may take upon themselves numerous shapes and configurations, viz., ovoid, oblong,

circular, irregularly spherical, etc. They predominate in the female sex, although males, as remarked above, are by no means exempt. *Pregnancy* is a predisposing factor in their development, but an exciting cause is necessary for their final appearance. This exciting cause is to be found in uterovaginal secretions of a leucorrheal nature, so commonly met in the early months of uterogestation. Then again, the nervous element plays an important rôle in their causation. Condylomata lata must not be confounded with papillomata lata, the latter being non-contagious in character. Moreover, other symptoms of syphilis are likely to be present at this particular juncture. They may also be ascribed to the presence of anemia or chlorosis. Vulvovaginitis and various dermatosis of the genitalia are equally responsible for the condition under consideration. They may also be attributed to friction between two adjoining surfaces, as the ischiorectal space and the inguinoscrotal fold, and to irritation due to the accumulations of offensive secretions in these localities.

Their pathology may be viewed as a proliferation of the tissues of the corium, maceration, and ultimate desquamation of the cuticle, and a slight transudation of serum in the delicate and abraided cutis. In short, they are ordinary warts, which have been deprived of their superimposed corneous covering and possessing slight moistures. They impart to the examining finger an unctuous feel. Some authors assert that there is a contagious element about them, but this has not been verified in the writer's experience. Cohabitation does not seem to transmit the lesions to the unaffected person.

The influence of the nervous system in this form of papilloma becomes again obvious, for there are cases on record wherein the sudden occurrences of papilloma molle is solely traceable to emotional states and hysterical paroxysms. They are more prone to make their appearance during the warm season and entail much discomfort on part of the individual thus afflicted, giving rise to subjective manifestations, especially pruritus.

The treatment is both local and systemic; all dyscrasias must be remedied and the causes favoring their productions removed. Washing the lesions with a mild solution of an alkali, both deterges and disinfects them, leaving a clean surface for the application of the remedial agents. Astringents and protectives may be used locally, as well as mildly stimulating applications. A very efficacious prescription is the following:

R Ac. salicylici 0.60
Zinci oxidi 4.0
Amyli 8.0
Pulv. talci.....20.0

or

R Thymolis iodidi 4.0
Bismuthi subnitratis 20.0
Lycopodii 8.0

If they are stimulated in the inguinogenital fold the adjacent surfaces must be separated by means of gauze, into the meshes, of which one of the above powders is thoroughly incorporated. No ointments of whatsoever kind should be used in this variety of wart, nor should any caustic agents be employed.

Papilloma Maligniforme.—This variety of papilloma is a most serious one, in view of the fact that it invariably culminates into malignancy. Although not a very common affection, yet if it does exist it is most frequently met with in middle aged or old persons, the male sex predominating. It commences as a moderately sized wart on the genitalia or their adnexa. It very rapidly increases in size and assumes considerable proportions, some of them attaining the size of a hen's egg. There are more or less subjective sensations accompanying it, such as slight burning and smarting. For a time they proceed without any gross alterations in their structure, when suddenly our attention is called to a slight maceration of their surface; a mucopurulent exudate may be seen to transude from between the corrugated projections, emitting a somewhat disagreeable odor. Ulceration soon supervenes and proves intractable, while the subjective symptoms become more and more pronounced. The inguinal glands enlarge; the patient assumes a cachectic, sallow appearance and loses rapidly in weight. In short, we have to deal here with an epithelioma, due to the malignant degeneration of a papillomatous growth.

The only hope of a cure is total extirpation of the lesion and the removal of the inguinal glands, with or without subsequent radiotherapy. We must rigidly refrain from any other methods of procedure, except perhaps exposures to radium, which has in a number of instances proven efficacious.

Papilloma Urethrale.—This is really an exaggerated form of granular urethritis, mainly located in the fossa navicularis, pendulous portion of the urethra and rarely in the membranous portion of the canal. They exhibit the appearance of soft papillomata and spring from the mucosa. If situated within the posterior portions of the urethral tract, they give rise to subjective symptoms upon urination, with a marked thinning or curving of the urinary stream. Urethroscopy is the only method whereby they can be recognized, and these are readily seen filling the fenestrum of the urethroscope. They are of a lobulated or corrugated character, of the color of the adjoining mucosa. Concomitantly the patient suffers from an acrid mucopurulent discharge, which examined microscopically may contain staphylococci and diplococci. Occasionally they are caused by a gonococcus infection.

The treatment consists in (1) their slow reduction in size by means of a 15 per cent. solution of silver nitrate urethroscopically, (2) reduction by the electrocautery in the same manner, or (3) ablation with a special urethroscopic blade, intended for such lesions. In the latter method there is considerable bleeding, but the instillation of adrenalin will soon check the hemorrhage. If the urethra is abundantly studded with the papillomata, the process is necessarily a lengthy one and may extend over months. Two or three urethroscopic treatments weekly will suffice, as too frequent séances may irritate the canal and cause subjective disturbances on micturition. Internally an alkaline with hexymethylenamine may be administered, so as to reduce the acidity of the urine passing over the partially healed lesions.

SOME IMPORTANT POINTS IN THE TREATMENT OF GONORRHEA, AND SOME OF ITS COMPLICATIONS.*

BY M. ZIGLER, M.D.,

NEW YORK.

INSTRUCTOR IN GENITO-URINARY AND VENEREAL DISEASES, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; CHIEF OF CLINIC G. U. DEPARTMENT, LEBANON HOSPITAL.

FROM a theoretical standpoint, the treatment of gonorrhea in the male is often considered most simple and easy by the layman, and I am sorry to say that the opinion of the doctor is not infrequently the same. Yet from a practical standpoint this disease or its complications is at times one of the most intractable of diseases. From a study of the various methods advocated for its treatment one can readily understand that no one method in the past has been specific. Even to-day we have no known specific. In some cases the patients seem to respond to any method. In other cases they neither respond to any one method nor to a combination of all methods.

In regard to the simplicity and ease with which some cases are cured there is no doubt that such is the case in a great many patients, and those are the cases we as specialists rarely see. As a general rule, we see the subacute, more often the chronic cases, after they have run the gauntlet of the entire therapeutic armamentarium of the various doctors under whose hands they have been, and yet are not cured of their disease. It is for this reason that I shall devote the greater part of this paper to the discussion of some of the salient features in the treatment of these resistant chronic cases.

Before going into a discussion of the chronic type of case I shall say something about the acute type. In the acute cases one has the patient take anterior injections by means of the hand syringe, one with a capacity of a dram or dram and a half, preferably made of glass so that the patient can see how successfully he is injecting himself. This syringe should have a rubber tip and a blunt point, to avoid the danger of breaking off a piece of the tip of the syringe and having it injected into the urethra. The patient is instructed to void his urine before injecting, in order to wash out the urethra, so that the medication can the better reach the mucous membrane, and, more important still, so that any pus that is in the urethra be not injected or forced back into the posterior urethra. The drugs mostly used to-day are argyrol, protargol, collargol, novargon, etc. These silver albuminates are in great favor to-day because of their non-irritating and strong antiseptic properties.

In treating gonorrhea to-day, we aim at curing the patient in the shortest possible time with the least amount of pain and suffering and with the fewest complications. Personally, I prefer argyrol to any of the other silver albuminates, because I have not alone found it less irritating in the great majority of cases, but also because I have positively found it to be most soothing to the very inflamed and painful urethra and at the same time it compares very favorably with the other silver preparations in diminishing the discharge and causing the

disappearance of the gonococci. Some cases respond better to protargol. The latter, in my experience, are in the minority. One cannot, however, lay down general laws for the individual case.

In the early stage of acute gonorrhea we have the patient inject himself either with 3 per cent. argyrol t.i.d., and receive a 5 or 10 per cent. injection in our office every day or every other day. The injection that we give in the office is with a Bangs syringe sound, or with an Oultzman. This is given only into the anterior urethra. The injection that the patient takes, and also the ones given in the office, are allowed to remain in the urethra about three minutes. If there is an undue reaction the time is diminished to one or two minutes. Later on, as the patient becomes less susceptible, the drug is allowed to remain in the urethra as long as five minutes. Also the strength of the injections that the patient gives himself are gradually increased to 20 per cent argyrol or 2 per cent protargol.

In those cases in which the patients are tolerant of protargol it is used in strengths varying from one-half of one per cent to two per cent. This is given as an anterior injection, in the same manner as argyrol, in gradually increasing strengths, commencing with a one-half of one per cent. solution and gradually increasing the strength and length of time the drug is allowed to remain in the urethra.

After the pus discharge has become serous in character and gonococci have disappeared or considerably diminished in number, and the urine contains considerable mucous shreds and very little pus, then one commences with astringent injections into the anterior urethra. Various preparations are used for this purpose, among which may be mentioned zinc sulphate, zinc iodide, and zinc chloride. I personally prefer the following astringent hand injection: Zinc iodide and zinc chloride, each one-half a grain, added to 2 ounces of water. An injection of this strength is given twice a day and allowed to remain in the urethra about two minutes. If this is well borne, then the strength may be gradually increased to two grains of each of these drugs in two ounces of water. It probably would not be out of place to mention that in a good many of these cases we do not make a sudden change from the silver preparations to the zinc, but rather favor a gradual change by giving two silver injections a day, one in the morning and one at night, and in the middle of the day we give a zinc injection. This is done especially in cases where there are still a fair number of pus cells in the discharge, even though the mucous shreds predominate. The reason for making this gradual change is that we have found that where the change is made suddenly from silver to zinc that there is a sudden recurrence of symptoms manifesting itself by a marked increase of pus discharge. If the symptoms improve under the two silver and one zinc injection, then gradually two zinc and one silver are substituted, and finally three zinc injections. As the patient gradually improves under the zinc injections they are gradually diminished in frequency and the treatment of the posterior urethra is commenced.

In addition, during the acute or subacute period the patient receives antibleorrhagics or antiblenor-

*Read at a meeting of the Bronx County Medical Society, Jan. 16, 1918.

rhagics combined with the alkaline diuretics, such as the acetate, bitartrate, and citrate of potash, ten grains of each three times a day in water. In addition, the usual dietary orders—no alcohol, and a non-stimulating diet. One should advise cleanliness and bathing of the penis, also a suspensory for the testicles, etc.

There are some who recommend high Valentine irrigations, and still others who advise intravesical irrigations with various antiseptics. For my part, I simply mention these methods in order to condemn them because of the large percentage of cases in which complications follow their employment.

In taking charge of a new case, especially one that is chronic, it is important to emphasize the fact that there may be, and usually are, many factors that must be considered before the proper treatment can be given. A careful history is most important. Before going into the present history it is essential to take the past history. In taking up the past history one can readily divide this into two parts: first, family history; second, personal history. In going over the family history it is essential to inquire as to tuberculosis in father, mother, brothers, or sisters. Next comes the question of syphilis from parents, if this is obtainable. The family history having been inquired into, the next question to take up is the personal history, the past and also the present. The past personal history can conveniently be subdivided into two parts: first, infectious diseases non-venereal; and second, venereal. Under the caption non-venereal it is essential to inquire as to pneumonia, which may have been a tuberculous process; also ask if patient has ever been generally run down and was advised to go away for a rest, as this may possibly have been pulmonary tuberculosis. And also ask if the sputum has ever been examined for tubercle bacilli, and the results of the examination; also if the patient has ever been suspected of tuberculosis; also if the patient is subject to coughs and colds; also if the patient has ever had inflammation of any of the joints, especially the hip joint, which condition was suspected of being tuberculous, etc. Remember that there are two diseases which patients try to live down; the one is tuberculosis and the other syphilis. So, in taking a history on this point, always reserve an absolute decision for the future, and do not place too much reliance on a negative answer on these two points in the history. Typhoid fever should also be inquired into. Under the second division of past venereal diseases, syphilis should be inquired into. Chancroids, so called, are not infrequently initial lesions, so go carefully into the history of the same. It is essential to go into the details of the previous attacks of gonorrhea. Try to find out if the patient really ever had gonorrhea. Not all the patients who come with the history of having had gonorrhea have really had this disease. This you can be reasonably certain of by the history of onset. If the patient gives the following history of his supposed attack of gonorrhea, that the attack developed after four weeks' incubation, that there was no redness of the meatus, no burning at the tip of the penis, very little discharge, and that mostly mucous, and that this was his first and only attack outside of his present illness, you can be reasonably sure that the patient

never had gonorrhea, even though he may have received considerable treatment for his supposed gonorrhea. My reason for making this statement is that the gonococcus, in the great majority of cases, causes markedly acute symptoms when attacking a urethra for the first time. After a patient has had a number of attacks of gonorrhea the reaction may be quite slight, but it is not apt to be so when attacking what we call a virgin urethra. That is, one that has never been previously infected.

In following up the history still further, it is necessary for one to ascertain how many attacks the patient has had, the intervals between attacks, and what the symptoms were.

A very important point is the careful study of the past treatment of the patient. In this study you must go into detail as to what treatment the patient had, whether anterior or posterior, and the kind, and, if possible, the strength of the solutions used, whether irrigations, instillations, injections, sounds, or prostatic massage. Another important point is to ascertain the frequency of treatment, rather the interval between treatments; also the duration of individual treatments and the period over which these treatments were given. In other words, while taking the history one aims to ascertain, if possible, whether the patient has been over-treated, undertreated, or properly treated. In regard to the over or undertreatment of these cases I shall go more into details further on.

After one has obtained a complete past history one tries to obtain an accurate present history, paying particular attention to subjective symptoms.

After a complete history has been obtained the external genitals are examined. Not every patient who comes to you for the treatment of gonorrhea has that infection. So we inspect the external genitals for lesions. If there is a discharge under the prepuce we try to retract the same in order to look for possible lesions underneath. One then inspects the scrotum and abdomen for lesion or pediculi. If a discharge is present at the meatus a smear is immediately taken for gonococci. However, while doing so one inspects carefully the discharge as to its color and quality, whether purulent, serous, sero-purulent, sanguineous, mucous, etc.; also the quantity. In estimating quantity it is necessary to know how many hours' accumulation is present. This, of course, is judged by knowing how many hours previously the patient has voided urine. One then inspects the meatus to ascertain whether there is a narrowing of the same, also whether there are any false cavities in the meatus, with possible membranous partitions between. If so, these are cut at the very earliest convenience, because they may harbor gonococci, for even though the rest of the urethra may be properly medicated, and eventually cured, these small pockets remain a favorite resting place and focus for the diplococcus of Neisser. One also looks for enlargement of the glands of Littre. The testicles are inspected and palpated for enlargement, presence of thickening or nodulation in the epididymis, hydrocele, and varicocele. Inspection also will demonstrate the presence or absence of inguinal adenopathy.

After this part of the examination is done with, the patient is requested to void his urine, so that one can obtain a general idea of its macroscopic

appearance. I again take the liberty of reminding you that in order to value the macroscopic appearance of the urine properly you must know how many hours' accumulation there is in the bladder. One has the patient void about one-half or one-third of a glass of urine in the first glass and about the same quantity in the second. One requests the patient to retain the remainder in his bladder until after the prostate and vesicles have been examined and massaged.

The next step is the examination of the post-prostatic rectovesical space. By means of the index finger in the rectum the prostate and seminal vesicles and the base of the bladder are mapped out. The doctor must be able to tell which prostatic lobe is involved, the consistency of the involved lobe, whether simply catarrhal swelling or purulent tumefaction, whether the inflammation is located entirely in the prostate or in the vesicles, or in both, or whether the entire post-prostatic rectovesical space has become thickened and hardened by a dense layer of connective tissue. It is just as essential for the doctor who practises urology to see with his finger tip as it is for the gynecologist to map out the organs in the female pelvis. After the prostate has been massaged and the vesicles stripped, the patient is requested to void the third specimen of urine, and this is also inspected for its general appearance. At the time that the rectal examination is made the base of the bladder should also be palpated for a possible new growth; occasionally stones have been palpated at the bladder base.

After one has come to a decision in regard to the post-prostatic rectovesical space, one then examines the urethra. First, one examines the urethra, as previously mentioned, for redness of the meatus, discharge, presence of pockets and sinuses. If on inspection one was suspicious of a sinus, one further verifies this observation by passing a fine probe into the suspected area and trying to find out the direction, width, and depth of the same. The next examination of the meatus is to test its diameter. Inspection alone is often deceptive as to the real diameter of the meatus. One often finds a meatus which appears normal, as if it would readily admit a 24 Fr., yet on an attempt being made to pass a 24 Fr. one will find a definite obstruction about half an inch within the meatus. The opposite is also true, namely: a meatus which looks very small will readily admit a good-sized sound. So that one must not rely on inspection alone. If the diameter of the urethra has been tested, and it has been found that a sound no larger than a 20 Fr. can be admitted, and if lesions are suspected to be present in the urethra, it is advisable to do a meatotomy. This is particularly apt to be necessary in the chronic cases, where, because of this narrow meatus, the patient has not been able to receive the proper dilatation, or where it is necessary to inspect the urethra through the urethroscope. In a few cases I have also found it necessary to perform a meatotomy during acute gonorrhea, when the opening at the meatus was so small that the patient's urethra could not drain properly.

After the meatus has been properly dilated it becomes necessary to explore the rest of the urethra. In a general way the first conditions that we look for are either granulation tissue or a later

stage of granulation tissue, namely fibrous tissue, called, because of its mechanical obstruction, stricture. We detect stricture by means of either the bougie à boule or sounds. If, with careful, non-forceful use of a sound one has a marked amount of bleeding, one can be quite sure that granulation tissue is present in the urethra. In regard to the detection of a stricture, one first attempts to pass a 28 or 30 Fr. sound; if this fails, then one tries a size smaller; if that fails, then one tries a size still smaller, and so on, until one finally passes the point of obstruction. The statements above made apply both to the sound and the bougie à boule. In using the bougie à boule one makes the diagnosis by meeting an obstruction as one tries to pass the stricture with an instrument which is too large, and then using smaller sizes until one finally passes. After having passed the point of obstruction, on attempting to withdraw the instrument one finds that the shoulder of the instrument is caught in the folds of the stricture and pulls backward as one pulls forward. In other words, the diagnosis of stricture by means of the bougie à boule is first made by meeting an obstruction on attempting to introduce the instrument and pass the same beyond the stricture, and then is confirmed after it has passed by finding that the instrument is caught in the stricture, and when one pulls forward on the bougie the fold of the structure pulls backward. In passing, I might say that the diagnosis of stricture can be subsequently verified by means of the urethroscope. Granulation tissue can be inspected; it looks similar to granulation tissue elsewhere in the body. Strictures look like white scar tissue.

If one has come to the conclusion that a stricture is present, or that granulation tissue is present, then the patient is to have a sound passed every five days, with gradually increasing sizes. The object of passing a sound in a stricture case is to dilate gradually so that the urethra will no longer mechanically obstruct the flow of urine. The object of passing a sound on granulation tissue is to iron out these granulations. After the patient is dilated up to 22 or 24 Fr. then one can pass an endoscopic tube and inspect the urethra, and if localized areas of inflammation are present they can be touched with 5 per cent. nitrate of silver. This can be done every 10 to 14 days by means of cotton on an applicator.

In a great many cases of chronic posterior urethritis, dilatation by means of the Bangs syringe sound combined with instillation of nitrate of silver solution, in strengths from 1/2000 up to 1/100 every fifth day, can be made with considerable benefit. Those cases of chronic posterior urethritis which receive instillations, and also the stricture cases which need dilatation, should not be instrumented more frequently than every fourth or fifth day. Yet it is not at all infrequent for patients to tell us that they had a sound passed every day or every other day into the posterior urethra. A prostate also should not be massaged more frequently than every fourth or fifth day.

As a general statement, one might say that there are two types of mistreated cases. First, there are those cases that are undertreated; second, those overtreated.

In the first class of cases, namely, the under-

treated, I might safely say are patients who come under the care of doctors who have an aversion to treating gonorrheics, but nevertheless undertake to treat them by sitting at their desk, not even allowing the patient to expose his penis so that an inspection might be made of the kind and quantity of discharge. No local treatments are given during the entire course of the disease. Sometimes only internal medication is given. Occasionally this kind of treatment is sufficient, and in spite of this poor management, and no treatment to speak of, the patient gets well; but in the vast majority of cases this treatment is insufficient, and a great deal of valuable time is lost, with the result that the gonorrheal condition becomes chronic and the gonococci are got rid of with great difficulty.

The other type of case is the overtreated patient. In this type of case the well-meaning doctor overdoes things and causes so much trauma by chemical and mechanical means at his disposal that at times the damage is almost if not entirely irreparable. The gonococci, after such treatment, are usually gone, but also the urethra. In addition, the patient has had many complications that might possibly have been avoided. Most of these cases, I might safely say, are those in which the patient has given himself too frequent injections, or solutions which were too strong. Those cases, however, which are under the doctor's orders are usually medicated too frequently rather than by too strong injection solutions. I have repeatedly obtained the history that during an acute infection the patient was ordered to inject every hour. Still other patients have during the acute stage received intravesical injections every day. Speaking of the subacute or chronic stage, these patients would report that they received sounds every other day for weeks at a time. The following is a report from my private records of a patient overtreated and overinstrumented:

Dr. XX, age 30, single; infected with gonorrhea. Was ashamed at the outset of his infection to consult any of his confrères, so treated himself. In his history he admits injecting himself with a hand syringe as often as the inclination seized him to do so, which was about eight or ten times a day. After the acute process had subsided, he consulted a friend of his, who massaged his prostate three times a week, for a number of weeks, until the entire process again became subacute and the patient became worried and finally a neurasthenic. I do not wish to cast any reflection on either of these men. I simply wish to emphasize the fact that it does not seem to be generally known that treatment at too frequent intervals is harmful. Dr. XX, who was the patient was one of the brightest men in our class at college and a very bright hospital intern. The doctor who treated him was also an excellent student and hospital intern and a most capable clinician, but when it came to the management of this simple case, both men lost their heads in an effort to effect a prompt cure. I explained to the patient that this was a case of over-treatment and advised cessation of instrumentation for a time. After which time I advised that he receive massage of his prostate every fifth day. Eventually he no longer had his neurasthenic symptoms, nor symptoms of his mechanical urethritis or prostatitis. To-day he is married and the proud father of a child.

These cases of overtreatment I believe fare worse than those of undertreatment, and I am sure that I would much rather handle a case that has had insufficient treatment than one that has been overtreated. In the cases that come under one's care where undertreatment has been given, the rational therapy quite naturally will be to commence to

give the patient proper local treatment, either anterior or posterior injections, or instillations, as the case may require. Usually commence with anterior and terminate with posterior treatment. It depends, however, on conditions present.

In cases of overtreatment the best thing to do is to stop all treatment and give some placebo or oleum santali internally, while one is watching the case to see how much of the discharge is chemical and mechanical reaction. In some cases one may have to refrain from giving treatments for two or three months. In some of these cases, especially if the patient is very much run down, one advises a rest in the country, and in that way one increases the recuperative powers of the patient. In the last-named type of patient one will often be surprised to find that after the patient has had a rest he will respond to treatment which failed to be efficacious prior to his rest in the country. After this rest from treatment, either in the city or country, one recommences with weak solutions applied at long intervals, as above mentioned.

Conclusions.—1. During an acute anteroposterior urethritis one is to give no injections either in the anterior or in the posterior urethra so long as frequency, urgency, or strangury is present, several authorities to the contrary notwithstanding. As soon as the posterior subjective symptoms disappear one can slowly and carefully give anterior medication; no posterior treatment, however, until only the morning drop is present and gonococci either very few or absent.

2. When the gonococcus activity in the posterior urethra has quieted down then one may give instillations or pass sounds as may be indicated, but never give posterior instrumentation any more frequently than once in four or five days; some cases only once in seven days, depending on the amount of reaction following each instrumentation. The same applies to massage of the prostate or stripping of the seminal vesicles.

3. In this paper I have attempted to lay down some general principles to be followed in the treatment of gonorrhea, the most important of which is conservatism. When one considers the pathological condition in the early acute stage, namely, that the gonococci are already in the deep layer of the mucous membrane when we see the patient, and in order to kill these deeply seated cocci it would be necessary to use a most powerful antiseptic, almost a caustic. If this were done, the mucous membrane of the urethra would be destroyed. On the other hand, one does not recommend ultra conservatism. That is, one does not recommend doing nothing. But mild antiseptics, such as argyrol, protargol, collargol, novargon, etc., are recommended, especially for the anterior urethra, during the acute stage.

4. In the chronic stage, conservatism is also recommended. In that, treatments in the posterior urethra should not be given at too short intervals, in order that there should not be too much chemical and mechanical irritation or trauma to the urethra. In the subacute or chronic stage, however, one may use silver nitrate instead of the less irritating drugs such as argyrol, etc.

5. It is important to emphasize the fact that a very careful history of the case is most essential to the proper treatment.

6. It is also important in the study of your case to ascertain whether the patient still harbors the gonococcus in his urinary tract, or whether he is suffering from both the presence of the gonococcus and the sequelæ thereof. In passing, it might be mentioned that in the great majority of cases of so-called gonorrhea the gonococcus is long dead, but the havoc that it has raised is still there. There are, however, cases reported in the literature in which the gonococcus has lived twenty and even thirty years. Several years ago I reported a case in which the gonococcus was present for eleven years, even though the patient had had treatment for a good part of that time. So do not exclude the presence of gonococci unless you have had numerous cultures made from the expressed fluids of the prostate and seminal vesicles, and also from the urine voided after these glands have been expressed.

Finally, I wish to say that I have not attempted in this paper to take up the entire field of the treatment of gonorrhea, but rather to emphasize some points that I considered important in diplococcus of Neisser therapeutics.

40 EAST FORTY-FIRST STREET.

MESENTERIC THROMBOSIS WITH 88 INCHES OF INTESTINE RESECTED.

By EDMOND BONNOT, A.M., M.S., M.D.,
ST. LOUIS, MO.

AFTER searching the literature, I find only two cases of very extensive bowel resection for mesenteric thrombosis with recovery. In the first one, reported by McGuire' (*Surg. Gyn. and Obst.*, Jan., 1913), amount resected was 336 cm. In this case, while recovery was good, bowel movement remained very frequent. In the other case, reported by Brougham' (*Surg. Gyn. and Obst.*, 1917, v. 782), the amount

resected was 345 cm. In this case recovery was good, but the patient lost weight, and after the operation the bowel movements were very frequent.

Mrs. W., married, age 28, rather tall, weight 140 pounds, in good physical condition. Patient had gained 20 pounds the last year; appetite good; bowels regular. Patient was operated on for a pelvic inflammation Dec. 20, 1916, at which time both Fallopian tubes were removed. The wound was drained for two weeks and the patient made a very rapid recovery; left the hospital in three weeks and remained in good health until Aug. 30, 1917.

The onset was sudden, the patient was just through eating a hearty meal; while still at the table she was taken with a sharp cutting pain in the epigastrium. The pain was so intense that morphine gave her very little relief; vomiting was frequent but not fecal. I saw the patient about 12 hours after the onset. Her bowels were locked and no results could be obtained with castor oil, enemas, olive oil by rectum, pituitrin, etc. There was only slight coloration of the enemas returned. The patient passed some flatus; no trace of blood, no abdominal distention, temperature 99°, pulse 90, no shock, only slight rigidity of abdominal muscles; still complaining of intense abdominal pain, the woman slept at short intervals to be awakened by violent pain. Ten hours later the above described condition was about the same, with added marked rigidity of the abdominal muscles; some modular masses could be palpated through abdominal wall. The diagnosis was not made before operation.

The patient was taken to the hospital within 24 hours from onset, the skin was painted with iodine, and an exploratory operation removed the scar of the previous laparotomy. The peritoneum was congested and there was much sanguineous fluid in the abdomen, numerous coils of small intestine with dark blue infarct being seen. These coils were bound down by many firm adhesions and were highly congested. An extensive V-shaped area of mesenteric infarct extending to the median dorsal attachment was seen after liberating the intestine from the many adhesions. The exact location of the involved bowel was not ascertained, as time was a factor for possible recovery, but as near as could be determined the lower end of the resected bowel was about 24 inches from the ileocecal valve.

A length of 88 inches (224 cm.) of gangrenous intestine, including the involved mesentery, was resected between clamps. The mesentery edge was closed by continuous Glover's suture and drawn purse-string fashion, obliterating the edge nearly entirely. The intestinal ends were united with a Murphy button. A soft rubber drain (piece of glove) was anchored to the mesentery and one was placed in the cul-de-sac. The wound was closed by approximating each layer with Van Horn 20-day No. 1 catgut doubled, and stay stitches of silkworm gut, applied according to the author's method⁴ over glass rods, leaving one rubber drain at each end of the wound. During the operation the patient completely collapsed, but revived after the administration of 700 c.c. of physiological saline solution intervenously. She was taken to bed under almost complete surgical shock. During the following 24 hours she was stimulated with neutral camphor oil. Digitalin and a hypodermoclysis of saline were given, also quinine muriate by the rectum according to the author's method.⁵ As a result of the quinine, peristalsis was reestablished and flatus passed freely within 12 hours. The patient had no nausea or vomiting or the slightest postoperative discomfort.

The only complication was a fecal fistula which discharged freely through both drainage openings on the sixth day, and the surrounding skin became very irritated. I found that by using castor oil freely about the wound it relieved this irritation entirely and skin became normal.

The drains were removed at the end of one week, the stay stitches were left in place 12 days. At the end of the third week the fecal fistula had entirely closed and the wound did not gap. At the end of the fifth week a radiograph was made showing the button still in place; two days later she passed the button, and went home the same day.

When the patient left the hospital she weighed 114 pounds; three months later she had gained 19 pounds. She is now feeling fine, she has about two bowel movements daily, good appetite, and no discomfort whatever. She has returned to housekeeping, doing all her own work.

Summary.—The reader will note that the complete operation was done at one stage, contrary to the plan at present advocated of first doing an enterostomy, followed later by intestinal anastomosis; also that the intestines were not irrigated, that seemingly there was very little absorption, as evidenced by the temperature and pulse chart, and that, aside from the traumatic reaction and some acceleration of the pulse, due to weakness, the temperature receded rapidly. The temperature rose, and the pulse became rapid and somewhat irregular after the appearance of the fecal fistula, due no doubt to peritoneal absorption.

No doubt the early restoration of peristalsis, with the resultant bowel movement (12 hours after operation), was due to the quinine by rectum, and to this was due the recovery.

GRAND AND PARK AVENUES.

The Battle Line and the Adrenals.—According to Sergeant life at the front favors in every way the super-vention of adrenal insufficiency—through traumatism, infections of all kinds, overwork. Hence suprarenal therapy has a wide field of usefulness.—*La Presse Médicale*.

THE PSYCHOPATHIC HOSPITAL IDEAL.*

By LAWSON G. LOWREY, A.M., M.D.,

BOSTON, MASS.

ASSISTANT IN NEUROPATHOLOGY, HARVARD MEDICAL SCHOOL;
CHIEF-OF-STAFF, PSYCHOPATHIC DEPARTMENT,
BOSTON STATE HOSPITAL.

WE have heard a great deal, first and last, of the psychopathic hospital *idea*, but only a very little concerning the psychopathic hospital *ideal*, and yet this is of fundamental importance as determining the value of the *idea*.

Broadly stated, the *ideal* of the psychopathic hospital must be *service*: service of a particular sort, but limited in its scope only by the limits of the field of abnormal mentality, in whatever way manifested. The opportunities for service are *medical*, *social*, and *public*, to adopt Southard's triadic analysis of hospital problems.

The *medical service* has a number of potentialities. First, the patient must be carefully studied from every possible point of view. The patient (or family or friends) has the right to expect the most searching analysis that can be made. Accordingly, such analysis must begin with the study of the entire background of the person—the family, the social and economic status, the past life of the patient, make-up, reactive possibilities, diseases, conduct disorders—all of the manifold factors which have determined the activities of the individual. Then the *status præsens* of the patient—physical condition, nervous functions, mentality, and mental functioning—must be thoroughly gone into, using all the aids which modern medicine has devised (the laboratory, lumbar puncture, the Wassermann test, psychometrics) until the *whole* individual—static, dynamic, and potential—is understood. Only in this way can we avoid the pitfalls of diagnosis, render a reasonably correct prognosis, and decide upon treatment.

In this connection, a word about records of patients seems important. All records should be objective, and as nearly complete and accurate as circumstances will permit. The ideal should always be to record accurately, concisely, and completely all that can be learned concerning the patient, leaving out personal interpretations. Stereotypy of records is very difficult to avoid—but it must always be remembered that each case is an individual—and so our records must vary somewhat. Care must be taken that all abnormalities are obtained and are correctly ascribed to their proper fields of mental activity. Records should be so objective and so complete, so analytic and so synthetic, that a later reader can get the facts without feeling everywhere the personality of the examiner.

An important part of medical service is research—experimental, laboratory, psychological, clinical, and pathological. Psychiatry as a science is yet young; the lines are not closely drawn; the possibilities are enormous. Only by much carefully conducted research can we hope to benefit those who are now mentally sick, or learn how so to order the reactive life of the mentally well that they shall not become mentally ill. Everywhere in the world is the search for causes: in science, in social life, even in the problems of war. Causes are what we must seek in psychiatry.

*Psychopathic Hospital Contribution.

The psychopathic hospital service must be educationally applied to the medical profession, to medical students, and in a mutually reactive way to the State hospitals. That which we learn, if of value to us, is of equal value to the State hospitals, and we in turn should learn from them. The profession as a whole is rather ignorant of psychiatry. Each specialty claims the same thing, and this statement is often regarded as undeserved criticism, yet it is not so to be regarded. The peculiar conditions under which psychiatry must be practised have led to the condition. How fundamental it is that students and physicians learn more of normal and abnormal mental life, of the importance of early treatment, of guiding measures for those who are potentially abnormal! All such educational measures react to the ultimate benefit of the patients.

So it appears that the medical ideal is threefold in application: the study and treatment of the individual patient; research into nature, causes, diagnosis, and treatment; education of the profession—all aiming to serve the patient.

A threefold division of service also appears in its social ideal. Here the problem is one of study and adjustment of the mentally abnormal in some social position; in other words, it has to do with the individual patient. Now, each patient usually is the center or a part of a social situation involving a family. This family is likely to need medical care, aid, or some form of social adjustment. The ideal is to see that this is received in all cases where needed. Furthermore, patients may often occupy a fairly normal place in society if correctly guided and helped. In this field, which may be spoken of as the socializing of psychiatry, lies the large opportunity of the immediate future, and this is the zone of effort and ideal of individual and group social service.

Finally, there is the great ideal of educating the lay public to the enormous importance of right living and thinking from the standpoint of mental hygiene; the pervading influence of the reactive possibilities of individual and crowd; the prevention of those diseases and excesses which may be destructive to normal mental life. The very foundation of this is the training of children: obtaining a correct physical and mental balance, proportioned activity, correct reactions.

The ideal of *public* service has to do with the medical and social service offered to courts, to educators, to various public and semi-public organizations in dealing with their human problems. More and more are judges, charitable organizations, etc., coming to see that problems of misconduct, poverty, etc., are very frequently problems of failure or abnormality of mental reactions, and they are realizing the value of careful psychiatric examination early, rather than late. This side of the socializing of psychiatry is advancing rapidly of late years. After all, how can corrective or helping measures be successfully applied if we do not know what we are correcting or aiding? Of what value is punishment to the feeble-minded or insane, or to the unjustified victim of a morbid impulsion? These things can be determined only by examination. This part of the ideal is extremely important, and the ground it is rapidly gaining is one of the encouraging signs of the times.

So it appears that the ideal of the psychopathic hospital is the highest possible type of service medical, social, and public, in the interests of the mentally abnormal, either as individuals or as groups; the determination of causes, the care, treatment or adjustment; the protection of the individual or of society; the education of public and profession; in other words, making a broad and vital contact between psychiatry and society, to the benefit of both.

74 FENWOOD ROAD.

Medicolegal Notes.

Action for Services Rendered.—Where it was undisputed that a defendant employer promised to pay for the plaintiff physician's services in treating injured employees of the defendant, and that the plaintiff rendered services of a value not disputed, and that part at least of the services were rendered after the promise to pay was made by the defendant, the New York Appellate Division holds that a judgment for the defendant was erroneous and a new trial was ordered.—*Rosenthal v. Greenberg*, 168 N. Y. Supp. 488.

Hospital's Liability for Nurse.—The Washington Supreme Court holds that an incorporated hospital, having no stock, organized to treat sick persons and authorized to perform gratuitous services, and also to exact fees from persons capable of paying, is liable, when a patient is injured by the negligence of a nurse, only for its own negligence, if there has been any, in hiring the nurse.—*Maguson v. Swedish Hospital* (Wash.) 169 Pac. 828.

Malpractice—Care Required.—The Oklahoma Supreme Court holds that the law imposes but one standard of diligence and that is reasonable and ordinary care. That, however, is a relative term; and what would be reasonable and ordinary care under some conditions would amount to negligence under others. The importance, delicacy, hazard, and moment of the undertaking all enter into the question as to what, under the circumstances, amounts to reasonable and ordinary care, and is a question of fact for the jury. In an action for malpractice the evidence was that the defendant before beginning the operation counted the sponges to a trained nurse who had been furnished by the husband of the patient and repeatedly admonished her to keep an accurate count of the number of sponges inserted into the cavity, and did all he could to impress upon her the importance of her accurately counting the number of sponges taken from the cavity, to insure that none that had been inserted remained therein. He asked the nurse, before closing the cavity, if she had counted the sponges, and if all that had been inserted had been taken out, and she assured him that she had counted them, and that they had all been taken out. It was also in evidence that this was an approved method, used by many leading surgeons, of keeping track of the number of sponges used in an abnormal operation. Under the law on diligence and the facts in the case the court adhered to its opinion originally filed (150 Pac. 139) that the defendant was not liable.—*Cassingham v. Berry*, 168 Pac. 1020.

Recovery of Money Paid Under Duress.—The Washington Supreme Court holds that where a physician, falsely charged with abortion, pays money demanded to avoid disgrace, and fearing a false written statement by a subject of abortion supposed to be dying, the compounding of a felony is not a defense in an action to recover the money.—*Bertschinger v. Campbell*, 168 Pac. 977.

Expert Opinion Testimony.—The North Carolina Supreme Court holds that a physician, testifying in an action for the death of a man run over by a train, having made a professional examination of the deceased immediately after the injury, was competent to testify that from the nature, condition, and position of the wounds he was of opinion that the deceased was lying down at the time of his injury.—*McManus v. Seaboard Air Line Ry.* (N. Car.), 94 S. E. 455.

Military Medicine.

Reclaiming the Maimed in War.—Major R. Tait McKenzie, R. A. M. C., delivered an address before the College of Physicians of Philadelphia, on February 6, on this subject. He said that when, in the spring of 1915, he presented himself at the Surgeon-General's Office in London, and during the course of the preliminary examination, mentioned that he had had some special training in physical therapy, the examining surgeon was not cordial, saying that if they listened to all the men who were specialists they would get nowhere at all. So McKenzie said, "Well, put me at something." At Aldershot he gained some insight of the work done by the Royal Army Medical Corps and the work was of an exceedingly high order. Although it has been said that the work of the base hospital is to treat the men surgically, in his experience the aim of the average officer in command of the base hospital is to get his beds empty just as quickly as he can to be ready for the tremendous number of men who may suddenly need urgent surgical attention.

At first the man leaving the base hospital was passed on to one of the Red Cross hospitals scattered throughout the country, where he was treated by the local physician, where he was nursed, very often, by the lady of the house and her friends, and rapidly and inevitably spoiled by every attention, by hero worship, and by general indulgence. In order to stop this demoralization of fine men it was found necessary to establish, not only hospitals, but great convalescent camps in which the men were kept under military discipline and received treatment directed to putting them into condition for the front; or, at least light duty. These camps had a capacity of from 4,000 to 5,000 men with a variety of conditions. There were, first of all, the nerve cases, men suffering from "shell shock," which is, of course, a very elastic term, covering both mental and circulatory disturbances. Then there were the debilities following dysentery and occasionally typhoid. There were innumerable wounds of all parts of the body and of all degrees of severity. If at the base hospital in France it is found that a man will require prolonged treatment he crosses the Channel and goes into a great base hospital somewhere in England. From there he goes to a convalescent hospital and then to a command depot or physical training camp, where he is put into condition to rejoin his battalion and return to the front. If he is never likely to be put in condition for active service he is kept under military control and note is taken of his profession or trade with the idea of returning him to civil life as a self-supporting man. In Canada, under the Military Hospitals Commission, he may be sent directly to his home or elsewhere for vocational training. If further treatment is required it is given in a special hospital. In the Command Depot at Heaton Park the officers were practically all men who had been wounded, or men over age. The wounds of these officers were interesting; one had a fragment of shrapnel in the heart. He was the star patient, and was x-rayed repeatedly for demonstration. One officer had part of the hand off;

another had lost an eye. There was a staff of masseuses and medical officers and in addition four civil practitioners to care for the casual sick. Four men blinded in action did splendid work as masseurs.

It was necessary to improvise many of the means for carrying out the treatment at first. One of the huts, for example, was turned into a hydro-pathic establishment. It contained a pool bath filled with water at a temperature of 94°. Cases suffering with irritable heart, respiratory disorders, or mental disturbance the result of shell shock were greatly benefited by these baths. Progressive gymnastic exercises also formed a part of the treatment for these heart conditions. The whirlpool bath was introduced by the French. The water enters at three places, runs around the side and produces a whirlpool action at high speed and is kept at a temperature of 112°-115°. It was used in the treatment of painful scars and painful nerve conditions. It was a frequent and very distressing occurrence to see men coming in, wounded in the shoulder, with the arm blue, cold, and very painful. Massage alone was quite impossible. With the limb in the arm bath for about twenty minutes the blueness disappeared and the greatest possible relief was gained. Men who had not been able to sleep were made comfortable and massage and other treatment were made possible.

In the early part of the war there were many injuries from the hand grenades, which were often caught by the men in the endeavor to return them before they exploded.

The faradic current was used for muscle testing and muscle development. The galvanic current and ionic medication were also employed. In cases where a piece of shell had taken away part of the muscular tissue of the arm or thigh ionic medication with saline solution and radiant heat was frequently used. The small hinged shoulder bath was of value in preparing the region for massage. Massage is twice as effective if the part is well prepared by hot water, radiant heat, or electricity. Some badly contracted scars are treated by radiant heat rather than by the whirlpool bath, where they show a tendency to become sodden and break down. If, however, radiant heat and massage are persistently applied about the region of the scar it can almost always be slowly and progressively loosened and softened. Ionic medication is also used for the softening of the scar. In a large number of stiffened joints it was found very useful to have some means of recording the amount of movement gained.

Because of the great number of wounds affecting the hand and arm there was more necessity of devising appliances for developing the various movements of this number than for any other part of the body. In devising these appliances it was made a rule to keep all stretching movements under the control of the patient as much as possible. If this control was not held by the patient there was danger of continually stretching or tearing and adhesion which make the latter end of the condition worse than the first. A stretching movement was worked out in this appliance for circumducting the ankle. This also was under the control of the patient.

For the more skillful movements the pulley and weight were used a good deal. The exercises were arranged in a series including stretching and voluntary movements and were done in a definite order. The men came in classes of ten or twelve at a time. They were then given gymnastic exercises in classes of thirty to fifty. Provision was also made for deep breathing exercises, applicable mostly to the gassed cases, for balancing exercises to steady the nerves of the shock cases and restore their sense of equilibrium and their courage. On alternate days the men were sent off on a two-mile march, and this was gradually lengthened until they got up to a six-mile march, which was considered sufficient to return them to their reserve regiment.

A few pictures were shown illustrative of the metal facial masks made to cover the deformities and enable the men to go about without attracting attention. Many of the men so disfigured become morbid because of the horror which they seemed to incite and some in their depression had even committed suicide. Plastic surgery has done much for these men. But in cases in which the nose is completely destroyed a cast is made of the face; a new nose is modeled in clay, and from a cast of this an artificial nose is made of copper, silver plated, and tinted to blend with the skin. It is usually held in place by a pair of glasses or by spirit gum. By such means the man is enabled to return to his work. In the loss of the arm there have been made many successful devices, or "salary hooks" as they are called. Artificial legs are also supplied and trades are taught so that many men coming to the hospitals are sent back with a vocational training which they before lacked, and thus a wound may be really a blessing in disguise.

About 40 per cent. of the men were returned to the front line, about 17 per cent. to the lines of communication, and about 15 per cent. to clerical work at home; so that, for military purposes, perhaps, 70 per cent. were returned. The percentage sent back, however, depends largely upon the need of men at the front. In England now, where there is a call for 500,000 men, every man who can carry a gun will undoubtedly be sent back. Here, where there is, and will be, an abundance of men, the percentage sent back will probably be very small. It must be, therefore, always a question of supply and demand. In the convalescent hospitals and camps there will be a vocational officer whose duty it will be to ascertain a man's qualifications and preferences in reeducation that these may be adapted to his ability and desire. Usually these hospitals are established near a university or other institutions of learning. For example, in Montreal, they are located in close proximity to McGill University. In farming countries the men take up such occupations as chicken and truck farming, bee keeping, etc. Only about 7 per cent. of the men need to learn a new trade. There is always the tendency among men to choose an occupation that will keep them in the city, and the great endeavor of the Government has been to prevent this. Nearly all the men without a trade want to become operators in a moving picture show. They are so accustomed to life in the

crowd that they are unhappy if they are alone.

In conclusion Major McKenzie said he had been much touched by a tribute to the Highland regiments paid by Major Greenwood, and it reminded him of a letter which he had received recently from a friend who had been visiting a hospital, telling of a young Scotchman fatally wounded by a shell. He said to her, "I was twice gassed at Ypres, once badly; I was sore wounded in the side, and I had my leg broken and my arm hurt, and they put me out of the army three times because I was under age; but," he said, "I ay got back." When you meet men with a spirit like that, the speaker said, there is nothing that can equal it in inspiration—or surpass it in courage and devotion.

Treatment of Fractures of the Jaws and Injuries of the Nose, with Special Reference to Military Surgery in Germany.—Hedlund has made three trips to Germany for the purpose of studying military surgery. In the spring of 1917 he was at Düsseldorf where there is an admirably appointed hospital for the treatment of injuries of the jaws, etc. Here he studied injuries of the face and from the wealth of material seen here and in part in other hospitals he has collected notes of 56 cases personally investigated. Naturally our knowledge of the types of injury in question and of the treatment of facial traumas has been greatly expanded, and we are able to lay down certain principles for the readjustment and immobilization of fractures of the jaws, as well as for the after treatment, when plastic work or bone transplantation is required. In pseudarthrosis or bony defects, autoplasmic work answers well, the bone to be taken from the projecting portion of the ilium. In other cases portions of clavicle or rib may be used, especially when flaps of soft tissues are required. Bone from these sources is adapted to cases in which there are defects in the mucosæ. The time is as yet insufficient to determine the type of end results and we do not know much about the ultimate fate of the bony transplant which may in certain cases undergo absorption. The use of silver or ivory inserts is not recommended, for these are very apt to come away. So-called temporary prosthesis is often required in both simple and plastic cases. Dental prosthesis is usually necessary, both for functional and cosmetic purposes. In rhinoplasty for nasal injuries the old Hindu method (transplants from the skin and bone of the forehead) and the modern European methods may all be useful. Free bone transplants from the ilium or tibia are used to form a bridge to the nose. The Italian arm method answers for soft flaps after the bony insert has been made. But the number of possible procedures is very large and thus far the author does not have any special indications, save that only autografts are used.—*Hygiea*, December, 1917.

Dysentery Among the British Troops in Salonica.—As may be imagined, there has been a good deal of dysentery among the British forces stationed at Salonica, the majority of these cases being of the bacillary type and amenable to treatment. In the *Lancet*, January 12, 1918, Major Duncan Graham of the Canadian Army Medical Corps

deals with some points in the diagnosis and treatment of dysentery occurring at this place. The dietetic treatment of bacillary dysentery, Graham says, is the most important factor in its cure. Serological examinations have shown that second attacks of bacillary dysentery are very seldom new infections, but relapses from previous ones which have not been cured owing to absence of efficient treatment. In bacillary dysentery the intestinal mucosa is sensitive to sudden changes of diet, and consequently it is not surprising when relapses occur in patients shortly after leaving hospital, the ordinary diet of beef, vegetables, and bread having been changed to one of bully beef and biscuits in addition to exercise. Changes of diet must be gradual and according to Graham the test of cure in a patient before returning to duty should be, "Can he, while undergoing moderate exercise, withstand the ration he will receive on leaving hospital without having intestinal discomfort?"

It is pointed out that in the treatment of the acute phase of the disease dehydration of the tissues must be prevented, the food must contain sufficient calories for the increased metabolism, and be easily digested and assimilated. The amount of fluid taken by the mouth is not sufficient to keep the body fluids normal or above normal, so that the administration of 300 c.c. of saline solution intravenously and a half-liter subcutaneously is necessary for the first few days in severe bacillary dysentery. In very toxic cases the substitution of 5 per cent. glucose in distilled water for the saline solution has a better effect. By this means not only is the required amount of fluid provided, but the heart is stimulated and an extra number of calories is supplied in the food. Milk should not be given during the first three days. At first the diet should consist of albumin water, gruels, and clear tea sweetened with lactose. Lactose is valuable because it supplies food calories as well as on account of its favorable action on the bacterial flora of the intestines. The diet should be gradually changed to one of arrowroot, malted milk, sour milk, or diluted ordinary milk, diluted lactose being continued. The mouth should be kept clean by washes and the chewing of a solid substance while the patient is still on a liquid diet. When mucus has disappeared from the stools, soft poached eggs and a couple of biscuits may be given, custards, pudding, and dry toast being added to the diet gradually. As improvement continues a more solid diet may be given, but it must be borne in mind that untoasted bread is a very disturbing factor and should be forbidden until the patient has become accustomed to a solid diet. Those patients who stay long enough in hospital should complete their dietetic treatment by being given the army ration of bully beef and biscuits, and should take a moderate amount of exercise. Graham draws attention to the importance of careful nursing of dysenteric patients, and holds that a competent nurse is an asset of much value in a dysentery ward. Unless there is supervision by such a nurse dietetic regulation cannot be properly enforced. The good-hearted soldier will share his last crust with his neighbor restricted to a liquid

diet, and this is generally the cause of the disappointing progress of the case.

Laboratory Course in War Service for Women.—With the cooperation of the War Service Committee of the Medical Women's National Association, a second course in medical laboratory work is offered to applicants who have the preliminary training in science and scientific methods obtained in a four years' college course or its equivalent. The object is to fit workers for war service in medical laboratories in this country and in Europe, whether they take the place of men who have been called to the front, or go themselves as members of a unit which may be called for active service here or abroad. Dr. William H. Park of the New York University and the City Health Department, Dr. Anna W. Williams of the Bureau of Laboratories of the New York City Board of Health, and Dr. Elise L'Esperance are in charge of the course, which will extend over a period of three months, requiring six hours' work each day. The New York University, the Health Department, and Cornell Medical College have offered the use of their laboratories. Classes will be limited to about twenty. Application may be made to Dr. Anna W. Williams, Research Laboratory, foot of East Sixteenth Street, New York City.

Another Attack on a Hospital Ship.—On March 10, for the second time within a fortnight, a German submarine has made an attack on a hospital ship flying the Red Cross. This attack was made on the Guilford Castle, which had on board 450 wounded men from German East Africa. While the ship was seriously damaged the wounded and the hospital staff were safely landed without loss of life.

Hudson Street Hospital for the Navy.—The wards of the Hudson Street Hospital have been taken over by the Federal Government and will be devoted to the care of men in the navy for the period of the war. There are accommodations for about 65 patients, and already 35 patients from the navy are being cared for in the hospital. The ambulance service has been discontinued. Dr. Hughes Bayton and Dr. J. P. Hoguet will continue as head of the medical staff.

A Maternity Hospital Bombed.—A Parish despatch reports that a German aircraft dropped bombs on a maternity hospital at Nancy. A bomb fell between two occupied beds but failed to explode. The French hospital authorities sent to the American Red Cross Hospital at Toul requesting that they remove the patients. Dr. Maynard Ladd of Boston, in charge of the American hospital, provided facilities and received all the patients within twenty-four hours. Dr. Robert G. Sharp remained on duty for twenty-four hours and all the nurses worked overtime to meet the emergency.

Ellis Island Turned Over to the Army and Navy.—An agreement has been signed by the Department of Labor whereby Ellis Island has been turned over to the army and navy for joint occupancy. It is the intention of the Navy Department to use its space for the accommodation of several thousand sailors pending their assignment to ships. The War Department expects to

establish temporary quarters for wounded men before removing them to permanent hospitals. The Immigration Service will be taken care of by the retention of parts of the property and the use of various steamship docks in New York harbor. It is possible for the Immigration Bureau to do this, as only about 60,000 immigrants a year now pass through Ellis Island, this being less than one-tenth the former number.

Lieut. E. W. Young and Lieut. G. S. Condit of the Medical Reserve Corps have been invalided home, the former suffered a fractured skull from a shell fragment on his third day in France, and the latter broke down under the strain of work just back of the battle front at Ypres.

Red Cross on Transports.—Announcement is made from the headquarters of the Red Cross in Washington that transports carrying American soldiers abroad will have on board representatives of the Home Service Section of the American Red Cross to look after the comfort of the men. These Home Service men perform two duties. First, they learn by personal conference the anxieties of the soldiers on board and forward knowledge of these to the home department, and, secondly, they send communications from the man in the service to his family.

Red Cross Traveling Laboratories.—Four fully equipped traveling laboratories, outfitted at a cost of \$52,000, have been in commission since December 1 for service at the various cantonments. The plans for these cars were furnished by the Medical Advisory Committee, the cars were built by the Pullman Company, and are maintained by the American Red Cross at a cost of \$1,200 a month. Their bases are Washington, Nashville, Chicago, and San Francisco. Whenever the head of the Army, Navy, or Public Health Service sees the need for the services of the traveling bacteriologists a car is despatched from the nearest of the bases.

American Women Physicians at the Front.—During the last few months thirty-four women physicians from all parts of the United States have been sent to Europe by the American Red Cross, all of them having passed through the New York office of the American Women's Hospitals. Not one of them has official rank, although she wears the military uniform. The American Women's Hospitals has not urged the commissioning of American women physicians, but they have felt that commissions would probably come when these women had proved themselves fully as capable in certain branches of war work as their brothers in the profession. The American Women's Hospital now calls attention to the fact, in connection with the subject of commissions for nurses, that it is even more of a handicap for the woman physician to conduct her work without a commission than it is for the nurses doing war service. The American Women's Hospitals will inaugurate a campaign on March 26 to raise a fund to establish hospitals and clinics in the allied countries to be conducted entirely by American women physicians and surgeons. The campaign will last for ten days. A woman physician in every State has been appointed by the committee to organize her colleagues for future service abroad and for immediate service in the campaign.

Bill to Commission Trained Pharmacists.—A bill has been introduced in to the House of Representatives designed "to increase the efficiency of the Medical Department of the United States Army and to provide a pharmaceutical corps in that department, and to improve the status and efficiency of pharmacists in the army." The bill provides that the proposed corps shall be officered by one pharmaceutical director with the rank of major, five deputy pharmacy directors with the rank of captain, and as many pharmacists with the rank of lieutenant as may be deemed necessary. The principal duties of the corps as outlined in the proposed bill are the following: To purchase all medical, laboratory, and hospital supplies required by the Medical Department; determine the purity and quality of all such materials; hold and dispense all liquors and habit-forming drugs; perform all diagnostic and chemical tests, and do first aid and other similar work when necessary. The advocates of the bill claim that it will add greatly to the efficiency of the Medical Department of the Army and will also free many army surgeons for strictly professional work who now spend their time in clerical duties.

Appeal for Gifts for Columbia Base Hospital.—The Columbia War Hospital, situated at Gun Hill road in the Bronx, announces that 600 patients are now being treated there. These are men from the draft camps all over the country and from the Regular Army. An appeal is made for gifts which states that the following articles would be most acceptable: Talking machines, with records; bookcases and books, games, wicker chairs, playing cards, tobacco, jellies, jams and fruits. Personal visits are not desired as they interfere with the routine work of the hospital.

Quarantine at Camp Dix.—Following the discovery of a case of cerebrospinal meningitis in the Officers' Training School at Camp Dix, two student companies numbering 200 men each have been placed under quarantine.

Devens Healthiest Camp.—Camp Devens at Ayer, Mass., is the healthiest National Army cantonment in the country, according to a statement given out at the base hospital recently. The sick rate is only 32 in 1,000. There are 913 cases in the hospital at present, including 46 cases of pneumonia, 14 of measles, 15 of scarlet fever, and 2 of diphtheria.

Trench Fever Experiments.—The American Red Cross Research Committee recently announced that eighty-eight Americans, all soldiers from the New England States, had volunteered to suffer from trench fever in order that the origin of the disease might be traced. "One cannot speak too highly of these volunteers," a member of the research committee said. "They were subjected, first of all, to the strictest surveillance, were put upon an extremely restricted diet while undergoing the first disagreeable experiences, and were in anxious suspense while waiting for the painful period of the disease to set in. It was this suspense that caused the only murmurs of impatience." The committee announces that as a result of these experiments it has been definitely determined that trench fever is transmitted by lice. The pathogenic agent has not yet been discovered, but whatever it is, it occurs in the peripheral blood, and most abundantly during the first forty-eight hours after infection.

MEDICAL RECORD.

THE OWEN-DYER BILLS.

SURGEON GENERAL GORGAS has a record of many memorable achievements, but there is none of them to be compared, in its far-reaching consequences, with what he did recently in Washington, when he appealed directly to Congress to pass the Owen and Dyer bills to promote the efficiency of the medical corps of the army. We say this advisedly and without exaggeration. It was a great thing to free Havana from yellow fever, it was a great thing to make possible the building of the Panama Canal, but a greater thing by far will be to insure the winning of this war against the conscienceless enemy of God and man and the would-be wrecker of civilization. Wars have been won with little or no aid from medical science, and it is possible that this one might be if all the armies were equally defenseless against disease. It is safe to say, however, that there is not one single fact in the way of sanitation, prophylaxis, and therapy, learned by Germany in pre-war days from the leaders in medical science in France, England, and America which she is not employing to the limit for the preservation of her fighting men. If we are not equally alert and medically resourceful we shall find ourselves in imminent danger of defeat through depletion of the man power by preventable sickness. Our allies must have our help now to win, but we can give them little help if our armies are decimated by disease as they were in the Spanish war. General Gorgas served during that war, and he knows from personal observation the intolerable conditions arising when the medical officer is snubbed and his recommendations overruled by medically ignorant line officers. It is to prevent just such evils that the bills giving suitable rank to the medical officers have been introduced.

What these bills aim to do, and how the army will profit by the increased rank and dignity of the members of the medical corps, the MEDICAL RECORD has already explained in its issue of February 16. We have since received from the New York Medical Section of the Council of National Defense a letter setting forth certain arguments in favor of adequate rank for officers of the Army Medical Department; these we reproduce in part as follows:

"Rank is to a medical officer what professional eminence is to a civilian practitioner. The higher his rank the greater his opportunity for instituting and carrying through large and effective measures for the sanitary protection and care of troops. A medical officer's authority is measured entirely by his rank, not by his professional ability. If his rank is not sufficient to insure great authority he will be unable to apply his knowledge and skill to the best advantage. The best of advice is no good unless taken and acted upon, and in the army it is not often taken and acted upon unless the adviser has sufficient rank to add the weight of authority to his advice. Great responsibility demands, and should be accompanied by, great authority. Those medical officers upon whom rests a large responsibility for the safety and comfort of many troops should be given authority commensurate with that responsibility. In the army this means high rank. The medical officer cannot have anything like a free hand unless his rank is properly proportionate to that of the commanding officer for the sanitary care of whose troops he is made responsible. The failure of England's Mesopotamia expedition is said to have been due to disease among the soldiers. The disease among the soldiers is said to have been due to a failure of the commanding general to accept the recommendations of the chief medical officer regarding their sanitary care. This failure to accept the recommendations of the chief medical officer is said to have been due to his lack of authority with which to impress the commanding officer. We ought to try to obviate the possibility of any such reports regarding the American expedition to France!"

If General Gorgas, by his bold act of insubordination succeeds in procuring the passage of these bills he will have once more shown himself a doer of mighty deeds. We entreat our readers to hold up his hands in this war-winning effort by telegraphing at once to their senators and representatives in Congress, urging them to vote for the Owen and for the Dyer bill respectively. And we beg of them not to stop there, but to make their patients do the same. It is the latter who have boys at the front and in the cantonments, preparing to go over, and it is to save the lives of these that the bills have been drawn. Every father, every mother, every wife of an American soldier should demand the passage of these life-saving measures.

SYPHILIS OF THE NERVOUS SYSTEM.

THE most dreaded effects of syphilis are manifested upon the nervous system, and therefore the main object of treatment is to overcome these manifestations. A good deal of pessimism is displayed with regard to the effective treatment of syphilis after it has passed a certain stage, and it is the general belief that dementia paralytica and long-standing cases of tabes dorsalis are hopeless and incurable. However, these are not the views of all.

The *Lancet*, February 16, 1918, publishes a lecture delivered by Surgeon H. Carlill, R.M., before the Royal College of Surgeons of England on February 11, 1918, in which he discourses in a very optimistic vein concerning the treatment of syphilis of the central nervous system. Of course, he, like all others, is insistent that a hopeful outcome of treatment of nervous syphilis depends very largely upon an early diagnosis, and he dwells upon the point that the outlook of sufferers from early nervous syphilis is now the reverse of dark, provided that physicians are constantly suspicious of a syphilitic basis of the symptoms and provided that they do not rest content until they have proved the presence or absence of the disease. Moreover, as said before, Carlill is sanguine that many even long-standing cases of *tabes dorsalis* may be cured by treatment. He concludes that the possibility of a syphilitic basis should be considered in every case of nervous disease. Nervous syphilis can be proved by the examination of the cerebrospinal fluid. The Wassermann reaction, however, is of little value in the diagnosis of these cases. Provided that the diagnosis is made early, and prompt treatment given in adequate quantity, syphilis of the nervous system appears to be curable in very many cases. The real result of treatment can be determined only by repeated examination of the cerebrospinal fluid, hence the absolute necessity of painless lumbar puncture. Some cases of curable meningo-vascular syphilis are diagnosed as incurable dementia paralytica, and treatment is withheld. Often, however, the precise diagnosis can be made only by watching the result of treatment, and therefore all cases should have treatment. In some cases of even long-standing *tabes dorsalis* the syphilis appears to be entirely curable by treatment, and in nearly all cases symptoms can be greatly alleviated by remedies of the salvarsan class. The outlook of sufferers from early neurological syphilis is very bright, and will be brighter still when the general standard of knowledge of neurological diagnosis is less inadequate than it is to-day. Indeed, Carlill says if the profession and the public learn to apply our present knowledge of syphilis and its treatment it is not too much to hope that future generations of students will learn of *tabes dorsalis* and dementia paralytica only from the textbooks. While, therefore, the real hope of curing nervous syphilis must still rest upon early diagnosis and vigorous treatment, at the same time it is encouraging to be assured by a man of Carlill's experience and knowledge that syphilis of the central nervous system, even in its later stages, is by no means incurable.

THE EVOLUTION OF GUNSHOT WOUNDS OF THE SPINAL CORD.

For convenience, the evolution of wounds of the spinal cord from missiles of war can be classified into three phases, namely, the phase of paralysis, the phase of reaction or inflammation, and a termi-

nal phase—that of aggravation or disorganization.

The symptoms of the first phase are pain, paraplegia, sphincteric disturbances, and decubitus. During the second phase, which can be looked upon as facultative, meningeal inflammation occurs when infection of the wound has developed. This inflammatory process may be merely localized, giving rise to a febrile reaction and spasms, and contractions in a limb, or, on the other hand, it becomes diffused, involving the cranial meninges, usually ending in sudden death of the patient, who will have presented all the manifestations of suppurating generalized meningitis. If the patient should survive this phase, the evolution of the wound enters upon the third phase made evident by disappearance of the reflexes, purulent cystitis, often with pyelonephritis, and a rapid extension of the decubitus. The latter accident results in death after a more or less brief delay.

The three phases, the succession of which culminates in death, are far from being always present. The patient may die during the second phase, or, in favorable cases, this phase may not develop, so that a partial or complete recovery may ensue. In these favorable cases the disturbances of the sensibility are the first to improve, while motility is little by little reestablished either partially or completely. The amelioration of the paralysis is slow in making itself manifest and in general recovery is imperfect. The subject will be saved so far as life is concerned, but he will always retain a partial infirmity.

The primary disturbances, which persist or even become more marked, are due to the absence of nerve-repair, to myelitis, ascending degeneration of the posterior tract of the cord, or descending degeneration of the anterolateral tract. Occasionally, even after this apparent partial recovery, tardy accidents may appear, such as ataxic symptoms, progressive muscular atrophy, hystero-epilepsy of spinal origin, and diabetes. Ocular disturbances (amblyopia) have even been reported, which are assumed to be due to an ascending meningitis resulting in nutritive disturbances of the retina and optic nerve.

Fractures of the spine without lesions of the cord may be followed by difficulty in movement of the spinal column, resulting from the formation of a voluminous callus.

Taken all in all the prognosis of medullary lesions would seem to demand the greatest reserve. At all events this would appear to be the conclusion from the experience gained during the past three years. However, laminectomy has proven to be a relatively simple operation when resorted to in non-infected wounds of the spine and has given some encouraging results.

Laminectomy is indicated in all cases of compression of the cord by either missile, bone splinter, or hematoma, likewise for extra or intradural abscess, and the earlier the operation is done the more hopeful will be the results. In incomplete or complete

division of the cord, laminectomy followed by suture will probably not darken the prognosis, but the results so far obtained are certainly not brilliant.

WAR SAVINGS.

AFTER the war is over international relations, as well as the political organization and the economic policy of the world, will be different from what they were previously. The old principle of *laissez faire, laissez aller* is being rapidly swept away by war efficiency, and it can never be resuscitated to the extent to which it prevailed before the present cataclysm. Under the system of *laissez faire* we admittedly tolerated a great deal of waste. We have built up an easy-going philosophy of spending and we indulged in a wastefulness equalled, perhaps, by no other nation. The grim realities of the present, in the face of the stupendous undertaking which we must carry to a successful finish, call for a revision of our theories of easy spending as fundamental for general prosperity. Economists have repeatedly pointed out that extravagant consumption prevented the concentration of labor and capital in basic industries. Now is the time for heeding their advice. We should put all our capital and energies into the industries which will make for the greatest effectiveness of this nation in the present struggle. All the non-essential things should be eliminated and a campaign of intensive saving encouraged. It is not only the advantage which accrues to the individual from practising thrift that is important. It is the increase in the productiveness of the essential industries which will ensue if the demand for the customary comforts shall have been materially decreased. In spite of our living in one of the largest communities of the world, we are governed in our expenditures by the standards prevailing in the immediate group of our friends and associates. We must conform to the requirements of the group with which we associate if we do not wish to be *déclassés*. The National War Saving Committee has very wisely recognized this sociological fact and is endeavoring to use the group as a means of enforcing saving. It is accordingly calling upon the associations of all kinds to organize thrift circles. The movement has been started recently and promises to bear excellent results. Physicians can help in this splendid work by stimulating such collective saving facilities in their professional connections and through such organizations as the hospitals and dispensaries. Further information on the subject may be obtained from the Executive Secretary of the Public Health Committee of the New York Academy of Medicine, who is Chairman of the Hospital and Health Section of the War Savings Committee.

ABORTION STATISTICS.

GOOD statistics of abortion are difficult to obtain because we have only official cognizance of such cases as reach the hospitals. In large cities, many abortions occur of which there is no official knowledge, and it is estimated that there is at least one abortion for every birth. In a small university city like Helsingfors the number of public cases ought

to give a better idea of the actual number. In the *Finska Läkaresällskapets Handlingar* for November last, Spoof publishes an account of 2,909 cases treated in the University Gynecological Clinic during 1901-1916 inclusive, but in 1901 the number treated was only 39, while in 1915 it had reached 418, a slight increase over 1916 (362). For the most part the increase was steady. Thus in 1903 the figure was 75; in 1908, 126; in 1911, 217, etc. Of the 2,909 cases of abortion, 786 were febrile. During the same period the total number of abortions treated in the public hospitals at Helsingfors rose from 39 in 1901 to 673 in 1916 (these figures include those of the Gynecological Clinic). There is also to be noted a decided increase in the frequency of febrile abortions—from 10 per cent. in 1901 to 38.4 per cent. in 1916. These figures are out of proportion to the increase in population, to the number of marriages, and to the number of births. The only conclusion which can be drawn from such figures is that most of the abortions nowadays are provoked. Some parallelism is seen between the increase in abortion and lack of employment. The proportion of abortions which there is reason to believe were spontaneous—30 per cent.—shows a remarkable constancy from year to year. Just why the spontaneous and provoked abortions should maintain a constant ratio while the total number increases rapidly is inexplicable. Nor is it at all intelligible why the ratio of febrile abortions should quadruple itself.

A NEW METHOD OF TESTING THE FUNCTIONS OF THE SPLEEN.

A PAPER with above title was read by Steiger before the Society of Zurich Physicians last November (*Correspondenz Blatt für Schweizer Aerzte*, February 9). The new method involves recognition of the leucocytosis—chiefly lymphocytosis—which follows the injection of adrenaline, and which may be shown to be a purely splenic reaction. In splenectomized rabbits the latter never occurs. The rationale is given as follows: The adrenalin excites the fibers of the splanchnic which innervate the splenic capsule and blood-vessels. The organ contracts, and lymphocytes are forced into the circulation. A man with sound spleen gives a strong leucocytosis after having received 1.5 to 2 mgm. of the drug. The total number of leucocytes is increased by 2,000 to 3,000, of which 50 per cent. are lymphocytes. The maximum reaction is three-quarters of an hour after injection. The reaction informs us as to the number and quality of lymph follicles present in the spleen. In Banti's disease, syphilitic cirrhosis, pernicious anemia, myeloid leucemia, etc., lymphocytosis is but slightly in evidence. A further use of the diagnostic adrenaline injection is in abdominal tumors, for in splenic tumors alone can a reduction in size be thereby obtained.

RANK IN THE MEDICAL CORPS.

THE opponents in the War Department and in Congress of the Owen and Dyer bills, giving higher rank to a few of the members of the Medical Corps of the army, assert that the creation of some seventy generals, which the bills provide for, would

disorganize the service and give disproportionate importance to the medical branch. But even then our army would be behind most of those of our Allies in this respect. The British Army Medical Corps, for example, has 1.10 per cent. general officers, the French 0.47 per cent., the Italian 0.52 per cent., and the Japanese 0.89 per cent. The United States Navy Medical Corps has the equivalent of 0.50 per cent. general officers; the United States Army Medical Corps has approximately 0.005 per cent. general officers! That is to say, in a force of 16,000 medical officers, it has one general. Is it unreasonable to demand that the Medical Department of the army be put on an equality in rank with that of the navy?

News of the Week.

The International Surgical Society.—It was agreed at a meeting held in Paris on November 3, 1917, of delegates of the International Surgical Society from Belgium, France, Great Britain, Serbia, and the United States of America, that: (1) The International Surgical Society be dissolved after the publication of the Volume of Transactions of the meeting held at New York City, April 14, 1914. Should any money remain after the publication of the volume, such money will be divided pro rata among members. Each member of the Austro-German group will receive his share; but the money belonging to members from other nations will be retained and applied to some object of scientific reparation in Belgium. (2) A new society will be created after the war on a similar basis, to be called the "Inter-Allied Surgical Society." Surgeons of neutral countries may also be elected members.

Surgeon General Gorgas Appeals for Passage of Owen Bill.—Surgeon General Gorgas, on March 15, appealed to the Senate Military Affairs Committee urging them to report favorably on the Owen bill, putting men of the Medical Reserve Corps upon an equal plane with the Navy Medical Corps as to rank. The passage of this bill would result in the creation of 70 new generals, 800 new colonels, and 1,700 new lieutenant-colonels. Surgeon General Gorgas was supported in his appeal by Dr. Charles H. Mayo and Dr. Franklin Martin. President Wilson favors the bill, while Secretary Baker, the War College, and the General Staff are said to oppose it.

Control of Milk Supply Urged.—The Children's Bureau of the United States Department of Labor has issued a bulletin calling attention to the results of underfeeding or indiscriminate food substitution in childhood. The report states that "Never before in the history of civilization has it been so urgent a matter that every child should have breast milk for as long a time as possible." The report emphasizes that it is the duty of every individual community to see that its children have milk of good quality, and in sufficient amount to assure their normal development. To do this the price of milk must be controlled or fixed, and the milk supply to infants and children carefully safeguarded. Poverty and ignorance of dietary essentials have been ever-present factors in the malnutrition of the young, and war conditions cannot fail

to increase the gravity of the situation and the difficulties of maintaining the health of the nation. European nations have found it necessary to regulate the sale of milk and cream; we should not be slow to follow their example.

Smallpox in New York City.—During the year 1917 there were 14 cases of smallpox in New York City, 11 of which were contracted out of town. During January and February of 1918 there have been five cases of small pox in the city, two of which were contracted outside of the city. The Health Department calls attention to the fact that the number of cases of smallpox contracted outside of the city by individuals coming to the city and traveling about freely before the nature of their disease is known constitutes a menace, and should be guarded against by stricter attention to vaccination and revaccination.

Henry Street Nursing Service.—Figures recently given out by Miss Lillian D. Wald, head of the Henry Street Nursing Service, in connection with an appeal for funds with which to carry on and expand the service, are interesting as demonstrating the value of such a service to the community. During 1917 these nurses have visited 32,753 patients in New York City. Among these were 2,500 children under five years of age suffering with pneumonia. The total number of pneumonia cases nursed was 3,899, the mortality rate in this group of cases being 8.7 per cent., which is considerably lower than the death rate from pneumonia in the best conducted hospitals. The settlement during this period cared for more than 3,700 mothers and 3,500 new-born babies. Almost 12,500 minor surgical dressings were made. The year's total work required 277,170 visits by an average staff of 135 nurses.

Public Health Service to Study Communicable Disease.—Secretary of the Treasury McAdoo has ordered the United Public Health Service to make an investigation having as its object the improvement of methods for the prevention and control of communicable diseases, especially near the army cantonments. The study will commence immediately, and will involve both laboratory and field work. The laboratory work will relate largely to the standardization and preparation of serums. The effort will be made to find a more reliable serum for cerebrospinal meningitis and to find an immunizing serum for this disease. Efforts will also be made to improve the serums used in the prevention and cure of other diseases.

School Inspection in Extra-Cantonment Zones.—Medical inspection of school children has been undertaken by the United States Public Health Service to prevent the carrying of communicable diseases to the troops. Such inspection has been undertaken in practically all the zones surrounding army cantonments. An officer is detailed to give his full time to the work, and has an office and the assistance of school nurses or other help. The expenses are met jointly by the Red Cross, the local health authorities, and the Public Health Service. In but few of the places where this work has been commenced had school inspection been previously practised, and in none had the full time of a physician been devoted to it. This undertaking is primarily for the protection of the troops, but at the same time

the other benefits to be derived from school inspection are not overlooked. While all the children in the areas around the cantonments are examined frequently for communicable diseases, they are also to be examined at least once a year for physical defects. When defects are found, the parents are informed, and urged to have them corrected. The nurses not only assist in making the examinations, but go to the homes, follow up cases of communicable disease and tell the parents how to prevent the spread of infection, look up children reported as absent, and give advice in regard to personal hygiene. An attempt is also made to determine cases of defective or retarded children, so that they may be given special instruction. Encouragement is also given to the teaching of personal hygiene in the schools. The work will be conducted with a view to interesting near-by localities in school inspection.

Dr. Wesley Grove Vincent has been appointed provisional assistant visiting surgeon to the Harlem Hospital for 1918—not physician, as was stated in a recent issue.

James M. Munyon, the manufacturer of the widely-advertised homeopathic patent medicines, died suddenly at the Poinciana Hotel, at Palm Beach, on March 10, at the age of 70 years. He is reputed to have been a millionaire, and to have spent more money in advertising his wares than any other patent medicine manufacturer.

Gifts and Bequests.—The will of Henry L. Einstein leaves \$75,000 to be added to a previous contribution of \$125,000 for the erection of the Lewis Einstein Memorial Pavilion at the Mount Sinai Hospital, New York.

Indiana State Licensing Board.—At the recent meeting of the State Board for Medical Registration and Examination officers for the coming year were elected as follows: *President*, Dr. J. M. Dinnen, Fort Wayne; *Vice-President*, Dr. A. E. Caine, Marion; *Secretary*, Dr. W. T. Gott, Crawfordsville; *Treasurer*, Dr. M. S. Canfield, Frankfort. A resolution was adopted at this meeting to the effect that hereafter only one examination for physician's license will be held each year, and that the examinations shall be in English only. At the last examination one applicant was examined in Greek, and several women applying for licenses in midwifery were examined in Polish.

Obituary Notes.—**Dr. JOHN FRANKLIN SOUTH-MAYD**, a graduate of the College of Physicians and Surgeons, in 1892, died at his home in Brooklyn, N. Y., on March 12, aged 49 years.

Dr. J. H. LAMPTON, a graduate of the Louisville Medical College in 1875, died of tuberculosis at his home in Springfield, Ky., on February 25, aged 64 years.

Dr. R. J. PATTERSON, for many years a practitioner of medicine in Bennettsville, S. C., and a graduate of the Oglethorpe Medical College, died at his home, on February 24, aged 82 years.

Dr. OSCAR J. RUSSI, a graduate of the medical department of the University of Pennsylvania in 1901, died from pneumonia at his home in Jersey City, N. J., March 9. He was formerly house physician of St. Francis College.

Dr. ANTHONY GEORGE BAKER died of pneumonia at Philadelphia on February 17 at the age of 61

years. He was graduated from Jefferson Medical College in the class of 1887, and he was physician-in-chief to the Chinese Medical Dispensary.

Dr. CHARLES SMITH TURNBULL died of pneumonia at Philadelphia on February 21 at the age of 71 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1871. He was for many years surgeon major of the First Regiment, N.G.P., at one time ophthalmic surgeon to the German Hospital, a Fellow of the American Academy of Medicine, a member of the Association of Military Surgeons of the United States, of the Philadelphia County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. LYDIA A. BICKFORD of New York, a graduate of the New York Medical College and Hospital for women, in 1894, died in that institution on March 9, aged 69 years.

Dr. CHARLES GIMBERNAT, who retired from the practice of medicine fifteen years ago, died at his home in New York City on March 16, aged 74 years. He was a graduate of Bellevue Hospital Medical College in 1860.

Dr. WILLIAM LEE HOWARD, a graduate of the University of Vermont College of Medicine, in 1890, died at his home in Boston, on March 12, aged 57 years. Dr. Howard was a graduate of Oxford University, England, and an Arctic explorer. He was a member of the *New York Herald's* North Pole expedition which sailed from San Francisco in 1879.

Dr. HOWARD J. WILLIAMS of Macon, Ga., president of the Georgia State Board of Health, and founder of the Williams Sanatorium, died at the latter institution on March 1, aged 60 years. He was a graduate of Jefferson Medical College in 1881, a Fellow of the American College of Surgeons, a member of the Clinical Congress of Surgeons, the National Public Health Association, the American Medical Association, and a number of other medical organizations, and was prominently identified with public health work in Georgia. Dr. Williams was chief surgeon to several railroads in Georgia, and was president of the Central Georgia Surgeons' Association in 1895, and of the Georgia Railroad Surgeons' Association in 1917.

Dr. REMUS CHARLES PERSONS died suddenly from the effects of a stroke of apoplexy at the home of a relative in Columbus, Ga., on March 4, aged 68 years. He was a graduate of Annapolis and of New York University Medical College, in 1872. He served in the Spanish-American War, and was stationed at the League Island Naval Hospital at Philadelphia at the time of his retirement from the service, about five years ago.

Dr. JAMES T. HENRY, a retired physician of Bentonville, Ark., died on March 2, aged 70 years. He was a graduate of the University of Nashville Medical Department in 1873.

Dr. CLARENCE L. HOWES, a graduate of the Dartmouth Medical School, in 1878, died at his home in Hanover, N. H., on March 7, aged 70 years.

Dr. L. K. WATERHOUSE, a graduate of the Eclectic Medical College, Cincinnati, in 1855, and the first coroner of Spokane, Wash., died in that city, on February 28, aged 86 years.

Correspondence.

TENT BURNING.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Instead of considering an "A" tent as something named for the letter A, why not imagine the first alphabet maker as taking the form of his tent for the first letter of his alphabet? For if one will but trouble himself to examine ancient picture writings, he may find there portrayed a tent such as we know it to-day. Arabs and Asiatics have been tent dwellers from prehistoric and ante-alphabetical times, therefore much lore has gathered about their form of dwelling. Notwithstanding all this, the art-form of burning tents while living in them is nowhere mentioned, pictured, or advised and would seem to be an acquirement of our own day.

If this setting fire to tents is a military game the first of its unwritten rules is that when a spark or brand burns a hole in the roof of a tent, then the man over whose cot that hole makes its appearance must rise immediately, must go outside at once, and must spread his shirt over the hole with the least possible delay lest the warm air escapes from the interior of the tent. Inasmuch as the pleurisy, pneumonia, rheumatism, and nephritis that will take hold upon a bare-footed, pajama-clad man, if he is exposed to the inclemencies of a northern winter, are really no part of the game, of course nobody is responsible; consequently the victims are turned over to the consideration of the hospital staff with little or no explanation and it must be admitted that that force looks after such patients with efficiency and silence.

Once upon a time a chaplain preached an eloquent sermon. In this he likened his hearers to those men who undaunted followed Moses in the great Exodus from Egypt. The preacher swayed and thrilled his audience as a real orator can, at times, and all went well until the following passages were uttered: "Moses and those men went forth for a mighty purpose, even as you. They went to do the will of a God not made with hands, and they dwelt in tents, even as you. And when that God showed his mighty wonders upon the Red Sea and stood its tremendous waters up like walls of glass on either hand so those men crossed dry-shod, it was to commemorate that marvellous occurrence to the latest posterity that Moses established a tabernacle, a great tent for the worship of an Almighty God, and this after the manner of tents he pitched due east and west even as you do to this very day." The audience would not let the gentleman proceed, for every one of the many tents in sight were pitched north and south. This naturally set the speaker to asking questions in reply to which a lady who was present volunteered the information that: "The sparks from the wood stoves did burn holes in the tents, though of course, by way of compensation a night view was very pretty; for an inside light shining through the holes reminded one of the candles upon Christmas trees."

Again, "Once upon a time" our country knew alcoholic days. Lots of men sang drinking songs even though they might not be drinkers. Here is a specimen of one called "My Pitcher."

A soldier's a man
Who'd be lost without rain,
He's a muddy amphibersome beast.
But he's got him a tent
Well pitched and well ditched,
And it's headed straight for the east.

Her air ain't so neat,
What with saddles and feet;
A goat couldn't have it no richer.
But she's dry and she's warm,
A good girl in a storm,
With nose-paint, fixins, and pitcher.

Many quotations from books upon army hygiene and upon kindred subjects might be used to show that the choice way of pitching a tent is to place it due east and west, and facing the east. If a tent is placed northwest and southeast, with a stovepipe chimney coming out somewhere in the north-north-west, about the only wind that might carry the sparks clear would be south-southeast; which is one of our rare winds. It usually blows when a change is in progress and the wind is shifting from southeast to southwest. A glance at the obelisk in Central Park, in New York City, will make this clear, with a little observation of what that stone records of the strength and direction of our prevailing winds.

Suppose that a tent were properly pitched with its closed end to the west and with its stovepipe suspended 18 inches below the ridge pole so that the pipe ran directly out through the east wall of that tent, instead of being run directly up through the roof. Then these advantages might be expected to follow: First, more heat inside of the tent because of radiation from the pipe. Second, sparks issuing from the pipe would be blown away by prevailing or usual winds, but even when adverse winds blew them toward the tent they would not fall upon the roof, but would strike against its front wall, and would, therefore, be apt to fall to the ground.

It is here admitted that the Arabs are tent dwellers using open fires for warmth during the chilly nights on the desert; yet they do not burn tents. But the Arab tent is a large square house-like affair, its wall or fall on any of its four sides can be removed. This enables the owner to remove the wall of the sheltered or leeward side where he builds his open fire and has smoke and sparks blown away from the tent that with three sides closed keeps out the chill wind and protects both man and fire. Arabian fuel is quite different from the wood of our camps in its capacity for giving off flying sparks and brands.

An "oracle" being asked why men were not instructed in the art of pitching tents replied, "In any army are plenty of tent makers; but you see a druggist is put to work in the commissary, a blacksmith is the buyer of drugs, and a tent maker is busy building a board walk. Each man knows what a dub he is at the job he is holding down, therefore he gives all his time to that job, and has no time to volunteer any suggestions along lines with which he may be perfectly familiar."

DOUGLAS H. STEWART, M.D.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

JIU-JITSU ADOPTED BY THE BRITISH ARMY—GENERAL DR. TUFFIER AND FRONT LINE SURGERY.

PARIS, February 22, 1918.

THE advocates for the introduction of jiu-jitsu into the physical training of our troops are more insistent and persuasive than its opponents, and, as the last word, have established the fact of its adoption by the British Army, and publish a communication from its sponsor, who said that when he was liaison officer in the British Army at the beginning of the war he immediately realized the interest of the jiu-jitsu in the hand-to-hand fighting, as he was before the war the amateur champion of jiu-jitsu in France. He therefore devised a simple method which he taught to the gymnasium instructors of the British Army and which has been spread all over the British forces. This method has been embodied in a booklet issued by the General Staff of the British Army, June, 1917, called "Methods of Unarmed Attack and Defense," and including three parts: (1) Simple method of unarmed attack and defense, etc., which can be taught to all recruits; (2) more advanced methods for military soldiers, etc.; (3) special methods for military police, etc.

It has proved very successful, first of all because it increases the morale of the army and gives the men the confidence that, even when unarmed, they can beat the boches, in addition to the healthy drill it gives them. Moreover, he says that every day he receives letters from his pupils of old, thanking him for the tricks he taught them and to which they say they have owed their lives.

The recent session of the Academy of Medicine was almost wholly devoted to an exposition by my eminent master and friend, General Tuffier, of the wonderful advances made in first aid and front line surgery. Dr. Tuffier is inspector general of the front and in an especially favorable position to judge of the work done and able to state the later results.

A résumé of his communication shows that 80 per cent. of the wounded are evacuated to base line hospitals, while 20 per cent. are operated on at the poste de secours, or first line ambulance. In general, the mortality rests at 5.16 per cent. and is caused chiefly by loss of blood, shock, or multiple wounds. The complication of gaseous grangrene appears in only three cases in 1,000 and tetanus 5 cases in 10,000. Wounds of the abdomen are always the most grave and cause death in 61 per cent.; those of the thorax show a mortality of 20 per cent.; wounds of the soft tissue, despite their almost universal contamination by dirt, hair, or clothing pushed into the wound by shrapnel, have a loss of only 17 per cent. He attributes the greatly improved results during periods of offensive movement, to the later perfection of the sanitary formations extending from the poste de secours on the line of battle in continuous line back to the base and interior hospitals; to the perfected service for rescuing the wounded from the field and means and lines of transport to place them at once in the character of ambulance suited to the gravity of their wounds; to the perfection of installation and equipment in these formations for the proper handling and treatment of all cases, and last but not least

to the perfect coordination of the entire service. In the early part of the war the various units, formations, and sectors worked independently, and employed systems and means favored by their heads, but now they have a unity of organization which insures the employment of a unified standard of technique, and not the least of which is the perfecting of methods of disinfection, the employment of primary suturing, and the universal and compulsory adoption of the Carrel method for the treatment of infected wounds. In concluding his exposition Dr. Tuffier averred that military surgery was at the present moment advanced to the greatest height of perfection, and all those who have someone dear to them at the front can have the comforting assurance that their medical and surgical care is as enlightened and perfect as any other department under Government control.

146 AVENUE DES CHAMPS ELYSÉES.

OUR LETTER FROM CANADA.

(From Our Own Correspondent.)

THE CANADIAN ARMY MEDICAL CORPS—NEW YEAR'S HONORS—MEDICAL EDUCATION AND PRACTICE IN ONTARIO—GIFT TO MCGILL—VENEREAL DISEASE REPORTABLE IN SASKATCHEWAN—PUBLIC HEALTH NOTES—DEPARTMENT OF SOLDIERS' CIVIL REESTABLISHMENT.

TORONTO, March 9, 1918.

IN a report recently submitted by Surgeon-General Foster, Director of Medical Services, to the Canadian Overseas Minister of Militia, it is stated that during the year 1917 the following units were organized or reorganized: Ten general hospitals, eight special hospitals, six convalescent hospitals, one ship hospital, two laboratory units, four sanitary sections, one central medical stores, two advance medical stores, one regimental depot and training school, and two administrative units. The personnel has been thoroughly sifted for the release of men fitted for general service. The total Canadian hospital capacity is now 19,950 beds.

Among the recipients of New Year's honors were the following members of the Canadian Medical Services: *Knight Bachelor*—Major Andrew Macphail, editor of the *Canadian Medical Journal* and the *University Magazine*. *Companion of the Bath*—Colonel F. G. Finley, of Montreal. *Commander of St. Michael and St. George*—Brigadier General C. E. Ashton, of Brantford, Ontario; Colonels Kenneth Cameron, of Montreal; Wallace A. Scott, of Toronto; George S. Rennie, of Hamilton; Walter L. Watt, of Winnipeg, and Lieutenant-Colonel J. A. Amyot, Professor of Hygiene in the University of Toronto.

On the occasion of the opening of the Toronto General Hospital, in 1913, the late Sir James Whitney announced that an inquiry would be made into matters relating to medical education and practice in Ontario. Mr. Justice Hodgins was commissioned to conduct the investigation, which has been most thorough and extensive. A report was submitted to the Ontario Legislature on February 6 last. It contains a number of important recommendations, among them being the following: That the practice of medicine be properly defined; that osteopaths, chiropractors, and other drugless healers practising medicine in Ontario prior to June 30,

1913, when announcement of the appointment of the Commission of Enquiry was made, be permitted to continue to practise until July 1, 1918, but that after that date no one be permitted to practise medicine in the province without a license from the College of Physicians and Surgeons, excepting those practising osteopathy on June 30, 1913, and holding a certificate from one of the five colleges recognized by the American Osteopathic Association, having had five years' practice in osteopathy, and having obtained a certificate from the Association that they are qualified to pass an examination for license in the State with the highest standard,—these may continue in practice under a special license from the Minister of Education; that optometry be taught in courses to be arranged by the faculty of medicine of the University of Toronto, the Optometrical Association, and the Toronto Technical School; that a clause be added to the Medical Act making it clear that there is nothing in the legislation to prevent the practice of the religious tenets of any church, but that any person practising such tenets for gain shall be required to obtain a permit from the Provincial Board of Health, certifying that the holder is required to be reported under the Public Health Act. It is also recommended that a Medical Director be appointed for the province; that the Constitution of the College of Physicians and Surgeons be amended (at present the homeopaths, about thirty in number, have five representatives, whereas the 2,500 to 3,000 members of the regular profession have only sixteen); that an institute of physical therapy be established on the premises of the Toronto General Hospital, of which the staff is to be selected from those who have had special training, particularly in war work, and that the necessary medical equipment for the proper instruction of students in physical therapy be installed in the Department of Physics at Toronto University and a compulsory course there established in physical therapy with a view to preparing qualified graduates; that independent examinations continue to be conducted by the College of Physicians and Surgeons and the Universities until the latter are prepared to delegate part of the degree conferring powers to the College; that surplus students of the Royal College of Dental Surgeons go to the University; that increased facilities for training such students be provided at the University, and that provincial registration of nurses be established with local branches where nurses may be registered according to their qualifications.

The sum of one million dollars has been presented to McGill University by the Carnegie Foundation in recognition of that institution's "devoted service and sacrifice toward Canada's part in the war." The gift is made as an expression of appreciation and sympathy for the people of Canada on the part of their allies south of the border. McGill has raised and equipped two batteries of siege artillery in addition to No. 3 Canadian General Hospital, whose splendid work in France is well known. Two hundred and thirty-six McGill students have already made the supreme sacrifice, and through its Officers' Training Corps the university has contributed over 2,000 of its own men and has trained 10,000 for service overseas.

Saskatchewan is the first of the Canadian Provinces to include cases of venereal disease in the list of contagious infections. Announcement was made recently by the Commissioner of Health that all cases of syphilis, gonorrhea, and chancroid must be reported by the attending physician within three days to the Commissioner of Health. The physician is required to furnish particulars as to the age of the patient, his occupation, marital relations, and probable source of infection. The name of the patient will not be stated unless he fails to return for treatment within thirty days, when his name and address will be sent to the Commissioner, who is empowered to take steps to insure that the patient receives the necessary treatment. Reports sent to the Health Commissioner are to be considered as strictly confidential and are not to be accessible to the public. Wassermann tests will be made and treatment given to patients at the pathological laboratory which was opened in January at the Regina General Hospital, and at the chemical laboratory of the University of Saskatchewan, Saskatoon. An educational campaign in respect to venereal disease and its prevention is being conducted throughout the province.

A bill was recently passed by the Saskatchewan Legislature to amend the Medical Act of that province. It provides that in future medical examinations shall be conducted by the University of Saskatchewan instead of by the College of Physicians and Surgeons, and empowers the College to grant permits to medical men from outside the province who otherwise are not qualified to practise in the province, to practise in isolated districts where it is extremely difficult for settlers to obtain medical attention.

The Alberta Government has passed an Order-in-Council which provides for the transference of matters connected with public health from the Department of Agriculture to that of the Provincial Secretary. The new arrangement will coordinate the various branches of health work. Questions concerning the establishment of municipal hospitals have been also transferred from the Department of Municipal Affairs, so that the board of health, vital statistics, and the establishment of municipal hospitals will all be under the direction of the Hon. George P. Smith, the provincial secretary.

Arrangements have been made by the Board of Education of Alberta to commence the medical inspection of children in rural schools as well as in urban institutions. It is proposed that teachers shall also be examined. At first only a couple of doctors and nurses will be employed for this work, which, however, will be gradually extended.

At the request of the New Brunswick Government, an investigation has been made by Mr. John Hall, a graduate of the Massachusetts Institute of Technology, into health conditions in that province. A report has been submitted by him which embodies a number of recommendations, and it is expected that the question of the establishment of a Department of Public Health will be discussed during the present session of the Provincial Legislature.

A report of the year's work of the health department was submitted to the Manitoba Legislature on February 8. The report calls particular attention

to the necessity for the early detection of cases of tuberculosis. During the year 1917, 307 cases of the disease were admitted to the Ninette Sanatorium, and of these 51 were apparently hopeless, 155 were already far advanced, 61 were moderately advanced, and 40 were incipient.

The Canadian Government has created a department to administer the work in connection with the reestablishment in civil life of those who have fought for Canada and the Empire in the present war. The name of the department is the "Department of Soldiers' Civil Reestablishment," which will be presided over by Sir James Loughheed, head of the Military Hospital Commission, who has been appointed Minister of Soldiers' Civil Reestablishment. The duties and powers of the new minister will cover: (a) The provision of institutions for the care and treatment of invalided officers, non-commissioned officers and men of the Canadian Expeditionary Force who have been honorably discharged, and the administration, control and direction of all such institutions; (b) vocational and reeducational training of all such discharged men; (c) the provision of such employment and assistance as may be requisite or advisable for such men; (d) all matters relating to pensions. The Military Hospitals Commission, with its staff, is to be continued under the name of the Invalided Soldiers' Commission.

2. The Treatment of Anthrax with Normal (Beef) Serum. Review of the Literature with Report of a Case.—Clarence H. Hyman and Timothy Leary review the literature of the serotherapy of anthrax, quoting Selaro, who reported a mortality of 6.09 per cent. in 164 cases treated with his serum, as compared with a mortality of 24.1 per cent. under other methods of treatment in Italy. Legge reported 12 English cases treated with Selaro's serum, with 2 deaths. Mendez of Buenos Aires claims priority in the serotherapy of this disease; he reports 1,073 cases treated with his serum, which is presumably similar to Selaro's, with a mortality of 4.19 per cent. Efforts to explain this apparently favorable action of immune serum have produced no satisfactory results. Kraus, Penna, Cuenca, and Solari, at the instance of the first named, have employed normal beef serum in place of the immune serum, with excellent results. In 146 cases of anthrax treated with injection of heated normal beef serum there was but one death, giving a mortality of 0.68 per cent. The authors report one successful case treated by themselves with normal serum. They conclude that, as before noted, no satisfactory explanation has been offered of the mechanism which produces the results obtained by immune serum other than the excitation of phagocytic activity, and this is not a specific immune response, but will follow the introduction of any foreign protein into the animal body. Whatever in the way of immune substances may be present in specific anti-anthrax serum, the amount of these materials must be very small. It is reasonable therefore to conclude that specific anti-anthrax serum owes its efficacy in small part to specific immune substances, and in large part to a non-specific protein reaction, obtainable by the use of other protein substances as well. Of these substances, the authors say, heated normal beef serum is, perhaps, the blandest and least objectionable.

3. Trichinosis.—James G. Cumming reports twelve cases of trichinosis in a family of thirteen, the nursing baby being the only one not affected. The symptoms ranged from a mild fever only in the younger children, to a temperature of 105° to 106° F. in the older members of the family, the temperature charts simulating those of typhoid fever. The family diet had been limited for the most part to dried fish, potatoes, bread, and milk, but about three weeks prior to the onset of the illness a hog had been killed. A part of the pork had been made into sausage, which was eaten in a partially cooked and in an uncooked form. The degree of illness was most severe in the older children, who had had unrestricted access to the sausage and had eaten it raw. The symptoms of muscle involvement were typical in those severely affected, and Eosinophilia was most pronounced in those in the early stages of muscle involvement. Gross specimens of the pork were suspicious of trichinosis, and microscopical examination elicited many muscle forms of trichinae. Treatment consisted in mild purgation for a couple of days, after which a liberal dose of thymol was given, followed by Epsom salts. The administration of thymol was followed in all the cases by a drop in the temperature almost to normal, with no subsequent rise. Whether or not this was due to a destruction and expulsion of the worms cannot be definitely stated. Cumming points out that if the benefit obtained from the thymol treatment resulted from a destruction of the intestinal forms of trichina, one would have to conclude that these, rather than the young migrating forms, were responsible for the elevation in temperature. No trichinae were found in stools after the thymol treatment.

4. Anthrax: A Case of B. Anthracis Septicemia with Recovery.—Roscoe R. Graham and Herbert K. Detweiler report in detail a case in which an anthracemia was present and was followed by recovery. The disease exhibited the characteristic four stages of cutaneous anthrax, viz., (1) The presence of an insignificant wound with no sign or evidence of danger which may remain as such for two or three days. (2) The appearance of a small pimple with a vesicle filled with a clear or blood-stained brownish fluid containing many bacilli, accompanied by the pricking or itching of the vesicle. This stage may last for from twenty-four to thirty hours. (3) Marked induration of the tissue underlying the vesicle, which has become flattened and has a livid color, marking the beginning of necrosis, which is surrounded by an edematous ring on which are formed vesicles which may coalesce. In the central dark eschar there are many bacilli. This stage lasts from one to two days. (4) More or less rapid increase of the dark slough along with the edema. The latter may be extensive and very widely spread. Here, because of secondary infection, it is difficult to demonstrate bacilli.

The size of this area is variable, and it bears no relation to prognosis. Other points of interest in this case were: The persistent increase in symptoms, and the presence of *B. anthracis* in the circulating blood, despite local excision and subcutaneous injection of serum. The sudden response to intravenous use of chloramin and serum in large doses, resulting in negative blood culture in thirty hours, and remaining negative despite the fact that no further specific therapy was used. The persistence of the edema of the skin and the slow healing of the wound, a black leathery eschar forming over the wound which did not disappear for seven weeks and then only when digested with a papain preparation. The edema persisted even longer.

5. **Nonrotated Ileum with Fatal Intestinal Obstruction Due to Occlusion of the Ileum by the Overriding Colon.**—Elmer D. Twyman describes a condition resembling that found in mobile colon, except that the ascending colon had overridden and become secondarily adherent on a coil of the terminal ileum; other coils of the ileum lay to the right of the ascending colon and cecum. That is, whereas the terminal ileum failed to rotate and descend, the cecum did so to the usual extent. It is probable that the condition was caused by a miscarriage of the usual embryonal shiftings of the intestinal tract. The patient gave a history of chronic "indigestion" with several attacks of diarrhea following periods of constipation. These attacks were succeeded by abdominal tenderness. The ileum in its retroperitoneal course was crossed by a number of fibrous bands and it is probable that a partial obstruction existed, which became absolute by reason of the swelling of the intestinal coats from an inflammatory reaction which caused the diarrhea, and the redness and swelling of Meckel's diverticulum. From a perusal of the literature, Twyman suggests the following groups of cases of nonrotation: (a) Nonrotation complete, of both large and small bowels; (b) Nonrotation, partial or incomplete, of both bowels; (c) Overrotation, causing pelvic position of cecum and appendix; (e) Malrotation, which may be normal in extent, but abnormal in that the colon comes to overlie or underlie some of the organs or membranes in a manner differing from the normal; (f) Nonrotation of the small intestine, or a part of it (that of the colon and the remainder of the small bowel having been normal in extent), of which the case described is an isolated instance. The case tends to support two theories previously advanced—that inflammatory adhesive processes in the peritoneum may occur in utero; and that, at least in some cases, fusion of the peritoneum on the back of the ascending colon to the posterior parietal wall does not occur until after full rotation and descent have taken place. It also illustrates a new phase of intestinal nonrotation; that of the small bowel alone.

2. **Carriers of the Meningococcus: A Year's Record (December, 1916, to December, 1917) of 26,543 Non-Contact Men Examined at Greenwich.**—P. W. Bassett-Smith, G. Roche Lynch, and S. Mangham reached the following conclusions from observations obtained from subjects of a large London Naval Depot during 1917: (1) For the year 1917 the carrier rate among healthy adult officers and men was about 4 per cent. (as com-

pared with 2 per cent. for the same depot, January to July, 1916). (2) The association of large bodies of men tends to favor the development of carriers, as shown by the greater number found among drafts than among new entries. (3) The importance of isolating known carriers as quickly as possible. (4) The highest incidence of carriers was in May, 1917, after which it fell, and no further cases were recorded up to the end of that period. (5) The great value of using a polyvalent agglutinating serum for the final diagnosis. (6) The relative preponderance among the naso-pharyngeal strains of Type 2 and the rarity of Type 3. (7) The occurrence of a considerable number of group agglutination reactions. The authors state their definite belief that the detection and isolation of carriers of any strain of meningococcus from large bodies of men segregated together is not only justified but necessary. An attempt was made to ascertain how far the differentiation into Gordon's four types of meningococci could be carried out with nasopharyngeal strains and it was found that the predominance of Type 2 was most marked; 132 out of 574 failed to agglutinate with any of Gordon's sera. Of 107 carriers who had more than one positive 47.66 per cent. showed a variation in the Gordon type in their subsequent swabbings, while 45.79 per cent. remained constant (6.55 per cent. were not examined). The curve showing carrier incidence for "staff" for the period October-November was practically identical for that of the "officers."

3. **On the Relative Advantages and Disadvantages of a Stiff Leg.**—Arbuthnot Lane points out that, contrary to general opinion, nonunion of the tibia to the femur is frequently an advantage and not a detriment to the individual, everything depending upon the habits of that individual. He suggests that when excision of the knee-joint is performed in civil life for disease or in war-time as the result of a projectile, the occupation, habits and wishes of the patient should be taken into consideration, and the surgeon should divest his mind of the idea that a stiff limb is the only result that he can hope for. Should the surgeon decide that a false joint is the best for his patient, enough bone should be removed to allow of the necessary range of flexion of the tibia upon the femur. The surfaces of the ends should be so shaped as to facilitate the formation of such a new joint, and extension and mobilization should be carried out by such a splint as that devised by Captain Watkin Williams. This apparatus has been in use for some time in England at Queen Alexandra's Hospital.

3. **The Modern Treatment of Empyema by Antiseptics.**—R. Atkinson Stoney points out that most, if not all, cases of empyema can be cured without resort to such mutilating and dangerous operations as thoracoplasty and pulmonary decortication, because it is not necessary to obliterate the pleural space, but merely to render its walls sterile, and this is possible by frequent washings with hypochlorite solutions. Flushing of the pleural cavity with hypochlorite solution is not dangerous provided there is a free exit for the fluid, as by the use of a double drainage tube. The earlier this treatment is instituted the sooner and more surely will a cure be obtained, as there will be less formation of granulation and scar tissue, and the organisms will not have had time to entrench themselves deeply in the tissues, and will therefore be more exposed to the action of the antiseptic. The drainage should be free and the opening should not be valvular; if a Carrel tube is used it should be introduced as far as possible into the pleural cavity through a large drainage tube, so that its fluid, starting at the most remote part of the

septic space, passes down over its walls and escapes freely between the Carrel tube and the drainage tube. The opening is most suitably made by removing one inch of the eighth rib in the scapular line, as this is the most dependant spot for practically all positions, and there is no fear of its closure by the rising diaphragm.

Berliner klinische Wochenschrift.

December 24, 1917.

Diagnosis in Renal Pathology.—L. Lichtwitz examines several procedures for determining the functional activity of the kidney. The concentration test he finds insufficient, as the density of the urine may be considerable even in cases of functional insufficiency. In such cases the total amount of substances which pass into the urine may conceal a real impermeability for the chlorides. The chlorides are always retained in greater amount than urea, for which product renal impermeability is generally very relative. Tests which compare the blood and urinary concentrations at a given moment give no data as to the maximum functional capacity of the kidney as they are too dependent upon momentary factors. Lichtwitz replaces these experimental data by the hourly study of the elimination, in a given quantity of water, of the chlorides and urea ingested. The tracings of the results thus obtained, with that of total diuresis gives a satisfactory notion of the renal capacity. Passing to the study of the repartition of the nitrogen bodies in the organism, the writer points out that they may be retained in the tissues without being detected in excess in the blood. The supposition that uremic paroxysms are due to cerebral edema is purely hypothetical. This examination of the renal function may very well have a direct practical importance, namely, the elimination from the list of chronic nephritides of numerous young men with albuminuria and hyaline casts who are otherwise perfectly fit for work or army service.

Cases of Dysentery with the Presence of the Pathogenic Agent in the Digestive Tract.—W. Nourcki reports four cases of dysentery, three of which came to autopsy. It was found that the agglutination test was frequently positive for the pathogenic agents of the dysentery. Blood cultures revealed the bacillus of Shiga-Kruse in one of the cases. The clinical aspect of all four cases was serious and evidently indicated a generalized infection. The spleen, however, was only slightly increased in size. The writer was able to demonstrate the presence of the specific bacillus in the urine in one case, and he insists on the importance of this fact from the viewpoint of epidemiology.

Münchener medizinische Wochenschrift.

December 25, 1917.

Steinmann's Method in the Treatment of Fractures of the Arm.—L. Warsaw says that in times of peace this method has been looked upon with some scepticism, but that the circumstances of war have imposed it upon surgeons. It is resorted to as a substitute for the usual methods of extension when they cannot be properly applied. The principal indications for its use are: (1) The extent of the injury of the soft structures; (2) the distal site of the fracture. The condyle can be nailed in place in supra-condylar fractures. The nail can be passed through the apophysis of the ulna in condylar fractures or those of the joint. For the introduction of the nails, no particular skin incision is indicated. Eight pounds is sufficient for extension and from two to three pounds are generally quite enough. Consolidation is complete and no complication has been observed by the writer. The duration of treatment is from three to four weeks.

Nervous Spasm of the Intestine.—E. Lieck desires to bring about a reaction against the tendency of operating on patients with intact appendices. He has seen operations done when there was no elevation of the temperature and no acceleration of the pulse. Such cases simulating appendicitis are, in reality, due to intestinal spasm, a fact which can be demonstrated by radioscopy. Many such patients have been submitted to removal of the appendix with a diagnosis of cica-

tricial adhesions. Atropine is quite enough to cure instances of intestinal spasm.

On Bedbugs.—Klingmüller points out that this insect is often the unrecognized cause of pruritus and urticaria, but it does not appear to be capable of transmitting contagious diseases. The nests of insects should be exterminated by alcohol, benzol, and soap and water. The flame of a blowpipe may also be employed.

December 27, 1917.

The Required Time of Isolation in Typhus Fever.—A. Pfeiffer considers that a quarantine of seventeen days is sufficient if one has sterilizers for the destruction of lice and proper disinfectants. When convalescence has begun Pfeiffer discharges typhus cases ten days after the return of the temperature to the normal.

Unsuccessful Results of Milk Injections in Surgical Affections.—A. Steiger is opposed to this new panacea lauded by a number of the profession. The patients that the writer has treated in injections of 10 c.c. of milk have in most cases in no way benefited from the treatment. Certain local affections (anthrax, boils, enlarged lymphnodes) reacted to the injection by a chill and rise in temperature lasting from two to three days. But the evolution of the process was never shortened. The writer is under the impression that stasis by Bier's method would have been more efficacious. In general injections the result was quite as disappointing. In a diabetic patient a very large amicrobic abscess developed at the point of injection.

Bullet Wounds of the Abdomen.—L. Reichenbach regards conservative treatment as utterly insufficient. The writer has had occasion to operate on these cases under all proper surgical conditions at a distance of five miles from the firing line, so that patients could be brought to him within an hour and a quarter after receipt of the injuries, although the time elapsed was usually longer. Estimating that the mortality of conservative treatment is 90 per cent. and that of operative treatment 70 per cent., or even less (the writer obtained 52.4 per cent. recoveries), Reichenbach concludes that surgical interference in bullet wounds of the abdomen should be resorted to whenever possible.

Scorbutus in the Russian Army.—E. Hoerschelmann studies the clinical evolution, complications and treatment of scorbutus. The following arguments speak against an infectious etiology: (1) The appearance of the disease in springtime when fresh vegetables are lacking and the disappearance of the disease when these can be obtained; (2) the absence of any data showing evidence of the contagious nature of the process, even in instances of cohabitation; (3) the immunity of officers who are rarely affected by scorbutus and this only when they partake of the trooper's diet.

Pyelitis Infantum.—Professor Wieland has treated 45 cases of this affection at the Basle Children's Hospital during the past four years, but in only 12 was the correct diagnosis made at the outset. This affection is almost a new one in literature, having until recently been confounded with cystitis. Not until 1896, at Escherich's clinic, was a supposed case of colicystitis found upon autopsy to be pyelitis. It is now known that at least 1 per cent. of all cases which come to clinics and physicians' offices suffer from this malady in a higher or lower degree, cystitis or nephritis naturally often coexisting. Although the author is writing of pyelitis in infants, only about half of the 45 cases occurred in early childhood, i. e., in the first three years of life. The remaining half of the cases, occurring between the ages of 4 and 15 years, may be regarded as a separate clinical entity. Twelve, or over a fourth, of all the cases occurred in nurslings, while in the entire series girls were attacked in the proportion of 7 to 2. It is important to note that all of the patients over 3 years old were girls, while in the first three years of life the boys outnumbered the girls 2 to 1. This fact emphasizes the dissimilarity of the two series of age groups. A survey of several cases shows how

the diagnosis is obscured. In the first two the children had lobar pneumonia, of which pyelitis was a sequela. The diagnosis was chronic pneumonia. Thus it is apparent that there is a group of postinfectious pyelites, which do not represent metastases but secondary infection with the streptococcus or *B. coli*.

Nature and Treatment of Tuberculous Ascites.—Gelpke refers to an article by Stocker on the surgical treatment of this affection, which represents a reaction against the medical management of these cases that economically is often a hardship. During two or three years required for a medical cure the patient's family becomes pauperized. In one case a man was sent to take a solar cure at a health resort, and after six months his state was so bad that he had to be sent home by automobile. The bill for the transportation alone was \$100, which loss bankrupted the family and exposed them all to a presumably contagious disease. This case could be duplicated 100-fold. The high sun exposure can be practiced at home, and has been ever since 1850. Exclusively surgical treatment is not advised. The author, who has thus far upheld Stocker, now reminds him that surgery has only a certain limited field in this affection, which does not comprise withdrawal of fresh exudate. It is a very ancient error, with which the profession has had one unfavorable experience. In 1896 the author pointed out this source of danger and has collected notes of 100 cases of this type in the practice of various surgeons in which not a single recovery resulted. Moreover, a recent exudate may be regarded as a salutary event in that the formation of antibodies protects the organism from further infection. But when these exudates have lost their protective power they should be removed.

Benign Tumors of the Breast and Their Relationship to Carcinoma.—Langenskiöld has carefully studied 31 cases of affections of the breast, which comprise 9 of fibroadenoma, 17 of chronic mastitis, and 5 of a combination of the two. The fibroadenomas are genuine tumors, composed chiefly of epithelium. Chronic mastitis cannot be regarded as an inflammatory affection, for the inflammatory element is purely secondary. In two cases the author noted the formation of granulation tissue. Nor can chronic mastitis be regarded as a blastomatous process, because of the great distribution of the alterations, which have their origin in apparently normally situated gland elements. The first perceptible departure consists of secretory phenomena and new formation of gland ducts which grow into the stroma. Then follow proliferation of epithelium and the appearance of a pathologic type of cell, the so-called pale epithelium, regarded by the author as quite characteristic of chronic mastitis. The epithelial proliferation leads to the formation of intracanalicular papilloma and large, solid tumors. Cyst formation through the disintegration of such is doubtless the most common manner in which cysts originate. There is much in favor of the theory that this proliferation is due to the activity of a hormone-like substance, probably a pathological secretion from the ovary. The author divides his cases of chronic mastitis into two groups, as follows: eight cases without macroscopic tumor formation and nine which show the latter (not fibroadenomata). In one of the first series a cancer developed in the same breast. In the second series there were four cases of malignant adenoma and three of carcinoma. The cancer morbidity of the 17 mastitis cases was therefore 8, or 42 per cent. The author concludes that when we see mastitis with macroscopic tumor formation we are practically dealing with cancer. What has been termed chronic mastitis, cyst-adenoma, etc., had best be regarded as a process peculiar to the mamma, like goiter in the thyroid, adenoma in the enlarged prostate, etc., etc. Cystic disease and dystrophy of the breast answer fairly well as names.

Extravesical Opening of the Ureter in a Woman.—Engström relates the case of a woman one of whose ureters opened into the vestibule. The ureter of this side was double, the other mouth opening into the bladder. The vestibular ureter was successfully implanted into the bladder by the intraperitoneal method.

The Sympathetic Nasofacial Reflex in Paralysis of the VII Pair.—Miraille and Emil-Weil refer to an earlier paper on the nasocardial reflex and announce the discovery that during the exhibition of this activity the face shows a peculiar reddening which is bilateral and prominent on the eyelids, forehead, cheeks and conjunctivæ, the latter showing vascularisation. There is also a secretion of tears. The reflex is elicited by exciting the pituitary membrane, and, as already stated, consists of two quite distinct components—the cardiac, which is expressed by a disturbance of rhythm, and the nasofacial. It appears to be present in all normal subjects, but is much more intense in certain subjects than in others. Various abortive types may be encountered, as isolated lacrymation. Only very exceptionally are the ears or the entire face involved. The extreme limit possible is attended by flushing of the neck and turgescence of the jugular. This great range of variation is doubtless the expression of the individual sympathicotonus. Since this reflex appertains to the trigeminal nerve, it seems evident that it should cause some modification in the innervation in facial paralysis. It might possess value in the differentiation of central and peripheral palsies as well as prognostic value. The authors have therefore instituted a number of experiments on subjects with facial paralysis. Naturally in a unilateral affection one side provides a perfect control for the other. The authors soon learned that the cause of the paralysis and the age of the affection are without influence on the reflex. In total paralysis there is no reflex elicitable. But when the affection has shown improvement this is at once apparent through the reappearance of the reflex in some degree. The entire reflex may return while the paralysis has only begun to show involution, and this dissociation has a hopeful prognosis. In eleven cases of central facial paralysis the reflex was retained throughout, as was to have been expected. In peripheral paralysis the trifacial filaments in the pituitary membrane are known to be hypoesthetic, but this is not the case in central paralysis. Moreover, the center of the reflex arc is in the bulb. The sympathetic fibres lie in the centrifugal portion of the arc, and the fibres seem to be blended with those of the lacrymal branch of the trifacial. The centripetal path is far less complicated and comprises only the afferent fibers of the trifacial. Finally, the sympathetic fibers in the centrifugal path accompany the branching of the facials.

The Intradermic Reaction and Its Prognostic Value in Typhus Fever.—Dumitresco-Mante refers to a recent claim that the cutireaction does not occur during the febrile period of exanthematic typhus. The author has therefore investigated the matter. As is known, this reaction is elicited with tuberculin. The author used the crude substance in a 1-100 solution on a material of 109 patients. Of this number, 45 were in the full febrile period. In 34 cases the result was completely negative, in 5 others feebly positive, and in 6 positive. Worth mention is the fact that in all positive cases the disease was of a mild type. Four patients who died gave a negative reaction. Of 7 patients tested during defervescence, 3 were negative, 2 weakly, and 2 strongly positive. Of 47 convalescents, all but 4 gave positive reactions. Finally the author tested 20 cases after death, and all were found negative except 1 weakly positive. The latter result was paradoxical, as all moribund patients reacted in the negative. To sum up, a positive reaction in a febrile or defervescent or convalescent patient is a good prognostic sign. Conversely, if the reaction is negative after defervescence, the general state of the patient showing no corresponding improvement, the outlook is gloomy, and if the reaction continues negative in a convalescent who has developed a febrile complication the prognosis must include the possibility of a fatal issue.

Antityphoid Inoculation and Addisonian Syndrome.—Sabre saw one patient in whom an injection of vaccine was followed by diarrhea, collapse, vomiting—in fine the entire Bernard-Sergent syndrome. No harm was done.—*La Presse Médicale*.

Book Reviews.

NERVE WOUNDS: SYMPTOMATOLOGY OF PERIPHERAL NERVE LESIONS CAUSED BY WAR WOUNDS. By J. TINEL, Ancien Chef de Clinique et de Laboratoire de la Salpêtrière. Preface by Professor J. DEJERINE. Authorized translation by FRED ROTHWELL, B.A., Lond. Revised and edited by CECIL A. JOLL, M.B., B.Sc., Lond.; F.R.S.C., Eng. Senior Surgeon Richmond Military Hospital; Assistant Surgeon Royal Free Hospital; Late Surgeon-in-Chief Majestic Hospital, Croix Rouge Française. Large octavo of 317 pages with 323 illustrations. Price, \$4.50. New York: William Wood and Company, 1917.

WHEN the great war began the number of injuries to the peripheral nerves that reached the base hospitals was far greater than had been expected; and as there had been no extensive studies of such injuries under war conditions, opinion as to the proper handling of such cases had not crystallized and the treatment in the individual cases depended to a great extent upon the amount of experience (or the lack of it) of the chief of the particular hospital which happened to receive the patient. The chaotic state which resulted soon stimulated interest and study on the part of leading French neurologists and surgeons, as well as those of other nationalities who had to do with these cases; and gradually certain surgeons learned not only when to operate but, what is almost equally as important, when *not* to operate.

In order to put this section of war surgery on a practical basis, numerous studies, both clinical and experimental, were undertaken, and the results of these studies were reported before various societies, particularly the Société de Neurologie and the Société de Chirurgie de Paris. One of the centers of investigation was the Charcot Clinic, where, under the direction of J. Dejerine, Tinel and others studied 639 cases, and this book embodies the results of their studies as well as those of many other workers.

Tinel's book is divided into four parts. Part I is devoted to a general survey of the field and includes chapters entitled: Nerve lesions in war wounds; Clinical examination of a nerve; Electrical examination; Clinical types; and General diagnosis of peripheral nerve lesions. In these chapters histology, physiology, pathology and all essentials of diagnosis in general are thoroughly discussed. Parts II and III are devoted to the discussion of injuries of the principal individual peripheral nerves of the upper and lower extremities respectively. Part IV has the caption "Conclusions" and is divided into three chapters entitled: Prognosis and treatment of peripheral nerve lesions; Surgical treatment; and Electrical treatment.

A vast amount of material has been reviewed in the preparation of this work, and, as Dejerine says in a preface which he has contributed: "The wealth and choice of the information offered, the carefully executed photographs, the numerous clear diagrams, make this volume a fine study in symptomatology, of great educational importance, and one which completely fulfills the purpose aimed at both by the author and by the publishers." This book, therefore, presents its subject in the light of the latest researches that have been made, and forms an invaluable guide to neurologists and surgeons about to begin work in war hospitals here and abroad; in fact, there are but few who have had so much experience that the careful study of this work would not add materially to their knowledge. The editor has rendered a signal service in making Tinel's work available to English readers.

DELUSION AND DREAM. An Interpretation in the Light of Psychoanalysis of "Gradiva," a Novel. By WILHELM JENSEN, Which Is Here Translated. By Dr. SIGMUND FREUD, Author of "Wit and Its Relation to the Unconscious," "Leonardo Da Vinci," etc. Translated by HELEN M. DOWNEY, M.A. Introduction by Dr. G. STANLEY HALL, President of Clark University. Price, \$2.00 net. New York: Moffat, Yard and Co., 1917.

A TRANSLATION of Wilhelm Jensen's romance, "Gradiva" is given here first, followed by Freud's commentary on the work. In the story a young archeologist has gotten

so far away from reality as to be on the verge of a psychosis, from which he is happily rescued by a sort of natural psychotherapy applied by a childhood sweetheart who happens to find herself in the favorable though precarious situation of being the center of his delusional field. The romance, besides being a phantasy itself, contains several dreams. Freud has pointed out how closely the artist in his creative efforts has followed the psychoanalytic teachings. To those who follow Freud this book will be fresh evidence of his genius; to his opponents it will be another example of his flights of fancy, unhampered by the ballast of logic. In any event, it is something new in literary criticism, just as his "Leonardo da Vinci" was in biography; and whether we agree everywhere or not, we at least find the book interesting reading. It is gotten up in a style uniform with the publisher's other issues dealing with psychoanalysis and related subjects.

INJURIES OF THE FACE AND JAW AND THEIR REPAIR AND TREATMENT OF FRACTURED JAWS. By P. MARTINIER, Professor to the Dental School of Paris, Dentist to the Seine Asylums, Honorary Director of the Dental School of Paris; and Dr. G. LEMERLE, Professor to the Dental School of Paris, Dentist to the Hospitals. Translated by H. LAWSON WHALE, M.D., F.R.C.S., Captain R.A.M.C. (Formerly Captain I.M.S.). The Oral Department, No. 83 General Hospital, B.E.F.; Visiting Surgeon to the Throat, Nose and Ear Department, The County of London War Hospital, Epsom; Laryngologist to the London Temperance Hospital, and to the Hampstead General Hospital. Price, \$1.75. New York: William Wood and Company, 1917.

THIS work is devoted almost entirely to prosthesis, and certainly covers the field in a most thorough fashion. We may also say that the translator has written about the most interesting preface that we have ever read. In this he calls attention to the importance of orofacial surgery at the present time, remarks upon the necessity of constant collaboration with expert dental mechanics, briefly criticizes some of the authors' views, and in conclusion says: "I should like to emphasize that facial work amply repays the trouble spent on it. Many of those maimed in this war will require, on their discharge, to canvass for civil employment. Human nature always finds physical deformity repugnant, facial disfigurement especially so. And the sufferers are apt to be handicapped if their appearance is revolting. Their recognition of this fact largely accounts for their extraordinary patience in undergoing the repeated operations which are necessary. Their gratitude afterwards is good to see. It gives the surgeon real pleasure to note the pride with which, let us say, a man who had lost his original nose sneezes through a new one made out of his own flesh and bone."

W hale has found that in treating gunshot injuries of the face and jaws the importance of temporary prosthesis is paramount, and that without its aid it would be impossible to get the results that are now obtained; but in the hospital to which he is attached permanent prosthesis is used as little as possible. The patient naturally prefers that loss of substance from the face be replaced by his own tissues; and Whale states that only one patient from General Hospital No. 83 has elected to go to England for a permanent mask prosthesis rather than undergo a series of operations.

The book is divided into three parts, entitled, respectively, External Prosthesis, Internal Prosthesis, and Treatment of Fractured Jaws. Methods of immediate and remote external and internal prosthesis are discussed in great detail, the descriptions being made still more clear by the addition of numerous illustrations. In the part covering fractures of the jaws old methods which should be discarded in civil practice but which are occasionally useful as emergency treatment are briefly described and properly condemned; while the new methods are described and illustrated in the most minute detail. Those likely to be called upon to do work in orofacial surgery will find this work extremely useful if not actually indispensable.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GYNECOLOGY AND OBSTETRICS.

Stated Meeting, Held January 22, 1918.

DR. WILBUR WARD IN THE CHAIR.

Wertheim Operations for Carcinoma of the Cervix.—Dr. IRVING S. HAYNES reported two cases of this nature.

CASE I.—This patient was a colored woman, thirty-six years of age, admitted to the Harlem Hospital on April 2, 1917. Her family and previous history, as well as her menstrual history, were negative. She had had one child, a normal puerperium, and no miscarriages. The last menstruation occurred on Feb. 1. She gave a history of irregular bleeding during the last three months, pain in the right sacral region and a whitish discharge. For two days before her admission to the hospital the bleeding had been severe. There was some pain on urination. At the time of her admission her temperature was 100.6°, pulse 128, and respiration 28. Physical examination showed the cervix occupied by a cauliflower mass as large as a lemon. Anteriorly this mass was ulcerated. There was apparently no involvement of the vaginal walls, bladder, or rectum. The uterus and adnexa were free and apparently not involved. The diagnosis was carcinoma of the cervix. On April 9, 1917, a complete abdominal extirpation of the uterus, adnexa, parametrial tissue, and the upper third of the vagina was done after the technique of Wertheim. First the cervical mass was thoroughly curetted away and full strength tincture of iodine freely applied. The anterior and posterior lips of the cervix were sutured tightly together over a packing of iodoform gauze. The vagina was swabbed with tincture of iodine. After clearing out the uterus and the rest of the tissues, the peritoneum was sutured entirely across the pelvis, completely closing the peritoneal from the vaginal region. A small iodoform wick was left in at the upper part of the vagina and reaching into the pelvic space beneath the peritoneum. The wound healed per primam and recovery was rapid and uneventful. The patient reported back for treatment several times and when last seen showed no evidence of recurrence.

CASE II.—This patient, thirty-one years of age, was admitted to the Harlem Hospital on September 27, 1917, complaining of continuous bleeding for the past four months, ever since a miscarriage, which occurred in May. She passed large clots of blood and had pain which radiated downward. The physical examination was negative except for the pelvic region. The cervix was taken up by a tumorous mass, which mushroomed like a cauliflower into the vaginal vault, involving the upper third of the vagina, and bleeding on contact. The tumor was 2½ inches in diameter and immovable. The body of the uterus and adnexa could not be made out, as the abdominal wall was rigid. By rectal examination, the tumor was felt to be close to the rectal wall, which was movable over the tumor. The parametrial and pararectal tissues were infiltrated. The diagnosis was carcinoma of the cervix involving the parametrium. At operation all the friable tissue was curetted from the cervix and the surface swabbed with tincture of iodine. Through a median laparotomy incision, a complete removal of the pelvic genital organs, with the upper third of the vagina, was done, following the Wertheim method. Care was taken to remove as much of the parametrial tissue as possible. The pelvic peritoneum was closed over a small iodoform wick left in the divided vagina. The pathologist's report showed that the growth was a carcinoma of the cervix. On January 20, 1918, the writer hunted this patient up and found that she was doing her own work without inconvenience. She had no symptoms except a slight whitish discharge.

Pseudohermaphrodite, Male Type.—Dr. ARTHUR STEIN presented this patient. He stated that the patient was thirty-one years of age, born and brought up in Finland; had never menstruated. Being aware that something was wrong with her and desiring to be married, the patient had sought advice, wishing to be

made a normal woman. He stated that he had always been attracted to men, never to women. A year ago he came to the hospital with the same request and at that time was submitted to laparotomy in order to determine the pelvic conditions. The records showed that there was no uterus, tubes, or ovaries, in fact, no female genitals whatever. At that time the appendix was taken out. The pelvis was that of a normal male. The entire physical make-up was entirely male in type. No adipose tissue was present, as one would expect in a female. All the muscles of the arms and legs were well developed. The breasts were perfectly flat, as in the male. The hair line was that of the female. Local examination showed that in the region of the left external inguinal ring there was a slight protuberance which proved to be a mass about the shape of an olive, movable to the left "labium majus." The mass was somewhat tender on pressure. The right "labium majus" was much larger than normally and contained an olive-shaped mass somewhat larger than the left tumor. The surfaces were those of a normal testicle, and the epididymis and spermatic cord could be easily felt. In the place of the clitoris there was an organ which in its entire make-up resembled a penis of the new-born type, about 1½ inches in length. The prepuce was well formed. The glans penis showed no opening. No vagina was present; in its place the perineum was found to stretch from the anus to the root of the penis, forming a firm raphe between the two "labia." The patient stated that erection and emission occurred. The urethral opening was to be found at the root of the penis on its posterior surface as a small pin-head opening. Upon rectal examination no prostate could be found. The diagnosis was rudimentary penis, hypospadias, undescended testicle on left side, descended testicle on the right side, absence of internal female genitalia, and absence of prostate. In this case it was not considered advisable to perform any operation.

Dr. ARNOLD STURMDORF said he did not think Dr. Stein intended to have this case go on record as a pseudohermaphrodite. It was very plainly one of arrested development of the male genitalia. The determination in general as to whether such cases were male or female was sometimes difficult, but in this instance one was not confronted by any confusing features. The patient had every objective physical evidence of being a male; all the organs and functions of the male were present, even to the production of the spermatozoa. The inclination toward the male sex was not necessarily evidence that the individual was a female, but an instance of perverted sex instinct.

Dr. STEIN said that he quite agreed with what Dr. Sturmdorf said and would change the title of his paper.

Prevention of Postoperative Retroflexion Following Operations for Pus Tubes, Résumé of Cases.—Dr. H. C. FALK made this presentation, in which he discussed briefly the possible causes of retroflexion following the removal of pus tubes, showing that the increased weight of the uterus, the stretching of the round and broad ligaments, with the excision of the round ligament at its origin, all tended to assist a posterior displacement of the uterus. The pus tubes when removed left a large raw area in the posterior cul-de-sac sigmoid and the posterior surface of the uterus. This raw area could rarely be covered by the peritoneum. It cicatrized and when the connective tissue contracted the uterus, being large and having very lax ligaments, tended to be drawn to a posterior position. Dr. Cherry of their service at the Harlem Hospital attempted to transplant omental fat to cover this raw surface, but found that in animals the fat was absorbed and replaced by dense connective tissue. In order to prevent these various causes bringing about retroflexion different means had been adopted. They had had in their service, in the last 200 cases, 54 cases with large pus tubes which were removed. Of this number 27 cases had been followed. A lock suture of the broad ligament was performed in 8 of the cases, with no special procedure to prevent retroflexion. Five of these uteri remained anterior and three were retrodisplaced. In three cases mass ligation of the broad ligament was performed; in all three cases the uterus remained anterior. Two cases had their broad ligaments plicated; they were equally divided, the

uterus in one instance remaining anterior and in the other becoming posterior. In one case the round ligament was brought in front of the uterus; this case showed a retroflexion. In three cases a Gillian operation was performed, in an equal number of ventral fixation, and in one a Coffey suspension. All three of these cases showed the uterus to be well placed in the anterior position. In summarizing it might be said that in 19 cases no definite procedure to prevent retroflexion was carried out; seven of these cases had a posterior displacement. In eight cases in which a definite procedure was followed only one had a posterior displacement. From their observation they therefore were led to believe that some method of suspension or fixation should be used to prevent a postoperative retroflexion.

Dr. ARNOLD STURMDORF touched briefly on one of the phases of uterine retrodisplacements which he had elaborated in a paper on "Congenital and Acquired Retroposition," read before the Section and published in the *American Journal of Obstetrics and Diseases of Women and Children*, No. 3, 1916, in which he called attention to a congenital form of retroposition normal to a certain type of skeletal contours and presenting the compensatory resultant of unstable intraabdominal dynamics. Such a retrodisplacement should not be converted into an anterior position. With normal spinal contours, the axis of the abdominal and pelvic cavities formed almost a right angle, while in the stature under consideration there was a marked flattening of the sacrovertebral angle resulting in an approximation of these axes toward the vertical, so that the thrust of intraabdominal pressure was expended in a more direct line on the pelvic viscera. This flattening of the sacrovertebral angle was regularly evidenced by a corresponding obliteration of the normal lumbar curve and the measure of its resultant approximation to the vertical constituted a pathognomonic index in differentiating congenital from acquired displacements of the uterus. A uterus congenitally retroverted before conception would invariably resume its retroverted position after delivery. It must be emphasized that congenital retroversion as such was essentially only a part of the compensatory adaptation of the pelvic contents to abnormal static conditions through unstable spinal poise; that the depth of the lumbar hollow was the relative measure of the sacrovertebral angle; that the degree of sacrovertebral angulation determined the dip of the pelvis, and that a certain degree of such pelvic dip was essential to the normal topography of its contents.

Dr. ARTHUR STEIN expressed the opinion that it was a very difficult question to determine whether a uterus was congenitally retroverted or not. When one saw a woman for the first time with a bilateral salpinx it was difficult to say that a retroversion which was present was congenital when it might just as well be due to the pathology present as a result of the pus tube. He thought it ought to be emphasized that in order to prevent a retroversion after an operation for pyosalpinx that we should suture the broad ligaments as Dr. Falk had described. They knew that if they did an operation for pyosalpinx the whole area around the uterus was swollen, inflamed, and edematous, and the ligaments were stretched, and if they took out the cause of all the swelling and edema the uterus and other parts would return to their normal size. So far as he knew there was nothing in the textbooks on this point, but he thought it a good plan to do as Dr. Falk described in all cases.

Dr. FALK, in closing the discussion, said that the chief point he was attempting to bring out was not the correction of retroflexed or posteriorly displaced uterus *per se*, but rather a method of preventing a posterior displacement of a normally placed uterus after the removal of large pus tubes.

Two Cases of Extraperitoneal Cesarean Section for Contracted Pelvis.—Dr. GEORGE L. BRODHEAD presented this report. He stated that the first patient, a negress, a primipara, eighteen years of age, was admitted to his service at the Harlem Hospital, on April 2, 1917, expecting to be confined on April 18. Her previous family and personal history were negative. Physical examination showed the uterus enlarged to the size of a full term pregnancy. Contractions were present. The

presentation was vertex; position R. O. A. The fetal heart was heard in the right lower quadrant. The measurements showed a contracted pelvis. The labor was protracted, the large head remaining above the pelvic brim making interference necessary. Operation was performed in April following the technique recommended by Dr. Cassasa, the assistant surgeon at the Harlem Hospital. This consisted in making a median incision just to the left of the navel, 2 inches above and 4 inches below the umbilicus, extending to the posterior sheath of the rectus and the peritoneum. A continuous lock stitch suture of plain gut was passed around the parietal and uterine peritoneum, so as to form an enclosed area of 6 inches in length and oblong in outline. An incision about 5 inches long was made into the uterus through this enclosed extraperitoneal layer. The membranes were ruptured, the child removed, and the placenta extracted. There was considerable oozing from the lower uterine segment. The uterine cavity was packed with iodoform gauze, the uterus was sutured with stitches of No. 2 chromic gut, and the skin with silk. The time of the operation was thirty-three minutes. The baby was born in good condition. For four days subsequent to the operation the patient had a temperature of 104.8° F. On the fourth day the wound was dressed and a small amount of seropurulent discharge was found coming from the upper and lower angles of the wound. On the sixth day after operation the patient had a temperature of 103.8° F.; she then made an uneventful recovery. Examination eight months later revealed an abdominal scar about 8 cm. long, one-third above and two-thirds below the umbilicus. The uterus was firm and suspended, or possibly fixed, to the abdominal wall. The cervix was closed, firm, and high up; the fornices of the vagina were shallow. The advantage claimed for this method was that the general peritoneal cavity was not entered at any time, the child being extracted through an area which was closed off from the general cavity by the suturing carried out in the early part of the operation. The second case was that of a primipara, twenty-five years of age, whose last menstruation occurred on March 1, 1917. She was examined by a physician on December 1, 1917, who told her she was over term and that labor would have to be induced. She was anesthetized and an unsuccessful attempt made to insert a bag. At the same time a dose of pituitrin was given hypodermically. After being in labor forty-eight hours, having had contractions every five or ten minutes, and having been examined by five different physicians, she was admitted to the obstetric service of the Harlem Hospital on December 3, 1917. She was in poor physical condition, exhausted, and emaciated. The vertex presented above the brim; the position was L. O. A. The cervix was only 1½ inches dilated. The symphysis pubis was very deep, and the space between the pubic arch and the sacrum very small. It was evident that delivery was imperative and the extraperitoneal method was chosen because of the many examinations the patient had had. The operation carried out was a modification of the technique recently published by Dr. T. H. Cherry in the *American Journal of Obstetrics and Diseases of Women and Children*, Vol. LXXVI, No. 4, 1917. A cubic centimeter of pituitrin was administered just before incising the abdominal wall. As the chorion was incised a foul smelling purulent fluid gushed out. The child was extracted by the breech, the cord clamped and cut, and the placenta and membranes removed intact. The bleeding was moderate, but was checked by pouring hot saline into the uterus and then packing it. A small opening above the uterus allowed a bit of the omentum to slip through; a plain catgut suture closed this aperture. After the uterus had been sutured by interrupted catgut sutures, a Lembert suture of the same material was used to cover over the uterine incision. The peritoneum was closed with a continuous catgut suture, the fascia by interrupted catgut sutures, and the abdominal incision by a subcuticular suture of No. 1 plain gut. The child, a male weighing over 7½ pounds, was born in good condition. After a slight postoperative disturbance and a slight superficial infection, the patient made an uneventful recovery. The scar in this instance was 3 inches long, half above and half below the umbilicus. The uterus was small and firm, the fundus at the navel

and apparently in suspension. The bacteriological examination of the amniotic fluid showed abundant staphylococcus, and blood cultures taken immediately after the operation showed the same organism and some contamination. Another blood culture taken two days later was sterile. Besides staphylococcus, a small gram negative bacillus was isolated from the amniotic fluid.

Extraperitoneal Cesarean Section for Contracted Pelvis.—Dr. E. C. LANGROCK reported this case, occurring in a primipara, twenty-five years of age, admitted to Dr. Brodhead's service. He stated that she presented a pelvis which in spite of normal external measurements had a contracted inlet. It resembled the male type and was markedly flattened on the right half. The patient had been in labor twenty-nine hours, in spite of which the head had not engaged. The membrane ruptured spontaneously at the beginning of labor and after twenty-nine hours the cervix was long and thick and dilated one finger. Because of the conditions enumerated, extraperitoneal cesarean section was decided upon. The patient had had many vaginal examinations. An incision was made in the midline, 6 inches long, one-third above and two-thirds below the umbilicus. The incision was made through the umbilicus in order to excise a small umbilical hernia. The first step of the operation was carried out as Dr. Brodhead had described in his first case. One cubic centimeter of pituitrin was given hypodermically and the uterus open in the midline. The baby and the placenta were extracted in the usual manner. The edge of the peritoneum was sutured to the anterior surface of the uterus, leaving an area of the anterior uterine wall exposed which measured $3\frac{1}{2}$ inches in width and $4\frac{1}{2}$ or 5 inches in length. The uterine incision was covered with a continuous suture of No. 2 plain gut. Except for a very superficial skin infection the patient made an uneventful recovery. The final examination of the patient showed the uterus adherent to the anterior abdominal wall over a small area of its anterior surface, while the whole of the posterior wall of the uterus, the fundus, and the anterior wall were left to enlarge in the patient's subsequent pregnancies.

Dr. GEORGE W. KOSMAK said he was interested in these case reports because of the high site of the incision, but he thought the term extraperitoneal incision was a misnomer for this, as in similar instances was a transperitoneal incision. It seemed to him that the uterus would involute more satisfactorily if there were no adhesions to the anterior abdominal wall. He had followed the method of Hirst in which the incision was made entirely below the umbilicus. He felt that with this method it was very easy to infect the peritoneum. On the whole, he felt that if he should get a similar case to those reported he would consider the facts very thoroughly before doing any more operations of this kind. At the Lying-in Hospital they had been opposed to the delivery of the uterus before emptying it, but he thought there were certain cases which had been examined frequently and handled a great deal in which cesarean section might be performed, but in which it was better to deliver the uterus before emptying it. In view of these drawbacks he thought the scope of the so-called extraperitoneal operation should be more limited and that in cases of this type there should be more hysterectomies done with the cesarean sections; there would then be no possibility of getting infection from leaving the uterus in position. Dr. Schumann of Philadelphia had recently suggested a delivery of the uterus through the abdominal incision and then closure of the abdominal incision, after which the uterus was opened and the vaginal stump, after the hysterectomy, sewed into the lower angle of the operative wound.

Dr. BRODHEAD disagreed with Dr. Kosmak. He said that if they had a patient like any of these three, who had been examined many times and when there was a strong probability that infection had taken place, he thought that if they could do the extraperitoneal operation without exposing the general peritoneal cavity to infection it was a safer operation and better than delivering the uterus before it was emptied. He could not see why one should take out the uterus in these cases, and he did not see how one could tell when a uterus was sufficiently infected to require removal. Furthermore, he did not see why the woman should not again become pregnant and carry to term. The

operation in his opinion would be performed more frequently in the future than in the past.

Dr. KOSMAK said that he had forgotten to mention that he had had the opportunity of doing two extraperitoneal sections in one patient. This patient had an infection of the wound after the first operation and a broad band of adhesions caused an anterior fixation of the uterus. The patient became pregnant again within two years and suffered a great deal of pain from the adherent uterus and from the fact that while the posterior wall expanded to accommodate the fetus the anterior wall did not. He did not think it was right to have left this woman with the anterior wall of the uterus adherent to the anterior abdominal wall and at the second operation he sterilized her.

Dr. HARRY ARANOW asked why they made the high incision. He said that, if he understood correctly, the reason for making a high incision in the classical cesarean section was to avoid adhesions. In a transperitoneal cesarean section where one deliberately attached the uterus to the parietal peritoneum there seemed to him every reason against a high incision. It was quite possible that the reason the doctors had hemorrhage in every one of these cases was because the uterus could not contract properly, being attached so high on the abdominal wall.

Dr. BRODHEAD, in reply to Dr. Aranow's question, said there was no reason why the incision should be made so high, and when he performed the next extraperitoneal section he meant to make the incision from the pubes to the umbilicus. Dr. Kosmak had spoken of the disadvantage of having the fundus adherent to the abdominal wall. With the usual cesarean section he had seen the uterus adherent and suspended from the lower part of the abdominal wound; this could not always be avoided, and if a low incision were made between the navel and the pubes the uterus would be suspended much lower than in their cases.

Post Partum Eclampsia.—Dr. F. A. KASSEBOHM reported this case which occurred in a patient 24 years of age, a IV-para, who was admitted to the Obstetrical Service on Oct. 7, 1917. He stated that the family and personal history were negative until four years ago, when the patient had pain over the region of the gallbladder, was jaundiced and had slight fever. The diagnosis made by the attending physician was appendicitis and cholecystitis. She had had three normal deliveries and three living children. Her present illness began on Oct. 7, at 6 A. M., when she was delivered of a normal vigorous female baby. Two hours later she had generalized convulsions and during the next hour she had several convulsions, and an ambulance was called. She had another convulsion on the way to the hospital. Physical examination when she reached the hospital showed the patient in a stupor from which she could be aroused only with great difficulty. The pupils were equal and reacted to light. The bulbar conjunctivæ were markedly jaundiced as was the skin of the remainder of the body. The pulse was 80 per minute; the blood pressure 122 systolic and 80 diastolic. Tenderness was present in the right upper quadrant from the costal border to three inches below the free border of the ribs. The edema of the lower extremities was marked, particularly over the dorsum of the left foot. A catheterized specimen of urine showed microscopically many fine and coarse granular casts, many red and white cells, and it boiled solid. The urea was three grams to the ounce. Bile was also present. The patient was given colonic irrigations with five gallons of 5 per cent. sodium bicarbonate solution, every four hours, alternating with a hot air bath every four hours. She was also given chloral hydrate per rectum after each irrigation. She continued to have convulsions during the night and in the morning was given veratrum viride, repeated every three hours until the pulse reached 60. The veratrum viride was given in hypodermic injections of 8 minims. She had five convulsions after this treatment was instituted. Three days after her admission the patient became rational and had had no more convulsions. Six days after her admission she developed a severe pulmonary edema during the night, became dyspneic, and respiration was shallow. The pulse was 120, temperature 100°, and blood pressure 170-110. Coarse bubbling râles were heard all over the chest, and the patient expectorated

pink, frothy sputum. A diffuse petechial rash, red in color, on a dry erythematous base and not disappearing on pressure was present over the upper extremities and over the chest anteriorly. She was then given morphine sulphate $\frac{1}{4}$ of a grain, atropine 1/150 of a grain hypodermically, and nitroglycerin 1/100 of a grain every 5 minutes for six doses; then every 15 minutes for six doses; then every hour. During the night she was given three doses of morphine, one-half the amount given above. The following day she felt better and the medication was to a large extent discontinued. That night the patient developed another attack of pulmonary edema more severe than that of the preceding night. The same medication was repeated and in addition a phlebotomy was done, 10 ounces of blood being removed. The pulmonary edema cleared up and the patient went on to an uneventful recovery, though some of the symptoms persisted for a time.

Dr. ARANOW asked how they knew that this was a case of eclampsia. Another point was that they gave veratrum viride in cases of eclampsia for the distinct purpose of lowering the blood pressure. Here they had a woman with a pulse of 80 and a blood pressure of 120 who had gone through an apparently normal labor and was giving symptoms of post-partum eclampsia. He could not see how she could have been improved by the administration of veratrum viride.

Dr. KASSEBOHM replied that the pulse was 180 when the veratrum viride was given and the next day it dropped to 150; it continued low until the patient developed the pulmonary edema when it went up to 170.

Cesarean Section for Eclampsia.—Dr. H. C. INGRAM reported these cases. He stated that the first patient, 30 years of age, a primipara, whose calculated date of confinement was Aug. 3, 1917, was admitted to the hospital on June 29, 1917, having had four convulsions prior to her admission. She was a woman weighing 200 pounds, and was markedly edematous and in a semi-comatose condition. The blood pressure was 196 systolic. Vaginal examination revealed a long, firm cervix with no dilatation, a very long, small vagina, and what was apparently a vertex presentation. The patient had five severe convulsions within an hour and a half after admission, so immediate emptying of the uterus seemed advisable. The abdominal route was chosen for the cesarean section and two male children were extracted, one weighing three pounds and twelve ounces and the other four pounds and six ounces. Both children were dead at the time of delivery. The uterus was closed by No. 2 chromic sutures and a Lembert suture No. 2 plain gut for the visceral peritoneum. The parietal peritoneum was closed by continuous No. 2 plain gut; No. 2 interrupted chromic suture was used for the fascia, and No. 2 plain subcuticular for the skin. Three silkworm gut retention sutures were also used. The patient was then put on colonic irrigations, chloral 30 grains, and a hot pack every six hours. She had no convulsions after the operation and was so improved by the fifth day that the irrigations were reduced to two daily. The patient's temperature was normal on the second day and remained so throughout. On the seventh day after the operation, when the wound was dressed, the escape of serous fluid was noticed at the lower angle of the wound. On the eighth day, after the patient had a coughing spell, the dressings became wet and the lower angle of the wound was found to be separated. This was packed with gauze. On the tenth day the patient complained of shortness of breath, suddenly became cyanotic and died. The necropsy showed partial separation of the abdominal wound and poor union in the remainder. There was a large amount of serous fluid throughout the peritoneal cavity.

The second patient was a primipara, 39 years of age, whose day of confinement was Aug. 2, 1918. She weighed 185 pounds. Her blood pressure was 160 systolic. She had a slight trace of albumen in the urine. She was put on a meat-free diet and forced fluid. On July 10, as she showed no improvement, she was sent to the hospital. Upon arrival she was very nervous and complained of headache. She was given colonic irrigations, chloral 30 grains per rectum, every six hours. On July 11 she had a convulsion lasting about six minutes. This was followed by four more severe convulsions within the next two hours. The

vaginal examination showed a long conical firm cervix with no dilatation and a vertex presentation. Abdominal cesarean section was deemed advisable. The high incision was used, one-half above and one-half below the umbilicus. A large amount of free fluid was found in the peritoneal cavity. The uterus was closed by two layers of No. 2 plain catgut continuous suture, then a Lembert of No. 2 plain gut for the visceral peritoneum. The parietes and peritoneum were closed by continuous No. 2 plain gut, the fascia by No. 2 chromic gut interrupted sutures, the skin by subcuticular No. 1 plain gut, and four silkworm retention sutures through the fascia. The patient was kept on colonic irrigations and chloral with the addition of hot packs. The following day she had two convulsions which were the last. The patient then improved, except for a slight rise in temperature on the seventh day, until the ninth day, when the dressing became wet and the wound was found to be separated. The patient was taken to the operating room and anesthetized. No signs of the former suture material were present. The edges of the wound were found separated and a sterile dressing pressed through the incision to the omentum. The edges of the wound were freshened by rubbing with a hot abdominal pad then five silkworm sutures were passed through one side of the abdominal wall, about one and one-half inches from the incision edge, through the fascia and the peritoneum and out on the other side. These ends were passed through split rubber tubing one on either side, making a lateral splint to the incision. The skin was closed by subcuticular No. 2 plain gut. After a slight temperature reaction the patient went on to recovery, being discharged on the fourteenth day in apparently good condition. One month after discharge she had a fine abdominal scar about five inches long. The uterus was free and well involuted.

Dr. STEIN raised the question as to whether a cesarean section was indicated in eclampsia, and whether a distinction should be made between the mild and the severe cases. In a mild case it might be that one could get along with the induction of labor with the Barnes bags, etc., but in the severe cases the best method was to perform an immediate cesarean section, although he felt convinced that even a cesarean section could not save all cases.

Dr. BRODHEAD expressed the opinion that the indications for cesarean section in some cases of eclampsia were very clear. In a primipara at term, with a long cervix, the induction of labor, the bougie, the bags, the lacerated perineum, and the post-partum hemorrhage, subjected the woman to greater risks than the cesarean section. The vaginal section was suitable up to seven and one-half months, but after that time it was better to use the abdominal section. Dr. Brodhead related an interesting experience with a wound that broke down several days after the operation and in which he found no trace of catgut left. In this instance he again sewed up the wound and gave a transfusion of 800 c.c. of blood. The patient then made a perfect recovery, the wound healing perfectly.

Dr. KOSMAK said that both this report and that of Dr. Kassebohm should receive most careful attention. Cesarean section for eclampsia in the first case would not have been required if the case had been treated by eliminative and sedative measures; he believed that woman would have been delivered spontaneously. Dr. Kassebohm's case proved that the presence of the fetus was not the decisive factor in the toxemia. The delivery in that case was perfectly normal and there was no evidence of toxemia at the time of delivery, yet the patient had a post-partum hemorrhage. In the second case there seemed to him no valid excuse whatever for an operative delivery in the presence of dead and premature fetuses. Such a course reflected on the operation and brought a valuable operative procedure into disrepute. He thought they ought to be very careful before they declared that most instances of eclamptic convulsions furnished an indication for immediate cesarean section. We should be very cautious about doing an operation requiring deep anesthesia and offering chances of infection and other serious complications in a woman already so dangerously ill and whose resistance was poor, when there were no contraindications to a vaginal delivery even if this were

delayed until Nature had been given an opportunity to complete the same.

Dr. ARANOW said the unqualified statement had been made that every eclamptic was best treated by cesarean section. He challenged that statement. Most of the best men in this country and abroad treated eclampsia conservatively. He believed that in the great majority of cases the woman who had one cesarean section would have to have a cesarean in all her subsequent pregnancies; he therefore felt that with rare exceptions the woman with eclamptic toxemia should be treated by eliminative measures, as Dr. Kosmak has described, until her uterus can be emptied with safety. Dr. Stein had stated that eclampsia was undoubtedly caused by the placenta. Dr. Kassebohm's case could not be said to have been caused by the placenta, as the symptoms appeared some time after the placenta was removed.

Strangulated Ovarian Cyst Complicating Pregnancy.—Dr. LANGROCK reported this case, which occurred in a patient 24 years of age, a primipara, whose last menstruation was on Feb. 28, 1917. She was first seen by the writer on March 17, 1917, for an attack of right iliac pain with vomiting. She gave a history of having had several similar attacks, which had been diagnosed as appendicitis. Vaginal examination revealed an early pregnancy and, as the woman was desirous of having the baby and the appendicitis was not particularly urgent, she was advised not to have the appendix removed at this time, but to wait until after her delivery unless she should have another attack. From this time her pregnancy was uneventful until Oct. 7, 1917, when she had another attack. There was slight tenderness in the lower quadrant but no rigidity and no mass could be felt either abdominally or vaginally. Appendicitis was diagnosed, but there seemed to be no indication for an immediate operation. Four days later the pain became very severe, the temperature rose to 101° F. and the pulse to 104. The blood count showed 19,000 white cells, 89 per cent polymorphonuclears, and 11 per cent mononuclears. Appendicitis was diagnosed and operation decided upon. The patient was removed to the Harlem Hospital and operated on by Dr. L. Friedman, who found a cystic mass the size of a large grape fruit. This mass was accidentally ruptured and a large quantity of bloody fluid escaped. The cyst was tightly pressed against the abdominal wall by the pregnant uterus and in this manner there was interference with the circulation. The pedicle extended to the right ovary. The inner surface of the cyst was hemorrhagic throughout and showed large areas of travasation and ecchymosis. The appendix was found acutely inflamed and was removed. The pathological conditions and the operation did not interfere with the normal progress of the pregnancy. The patient was delivered of an 8½-pound baby on Dec. 25, 1917, by a low forceps operation and had a perfectly normal puerperium.

Dr. BRODHEAD related the history of a patient referred to Dr. Haynes' Service at the Harlem Hospital and operated on by Dr. Falk. In this case operation revealed a large cystic mass extending to the right hypochondrium and having a pedicle going to the pelvis. The pedicle showed three distinct twists. It was trans-fixed, ligated, and cut. The pathological report showed a hemorrhagic, necrotic cyst wall. Dr. Brodhead said that occasionally in pregnancy they met with a fibroid with a twisted pedicle. He related such a case in a woman three months pregnant; in this case Dr. Grausman, who performed the operation, found a fibroid with a twisted pedicle and performed a hysterectomy.

A Rare Affection of the Lacrymal Passages.—Fava treated a young man who presented in the area of the left lacrymal sac a punched out ulcer having a greyish flow. On the adjacent cheek were three subcutaneous abscesses. A whitish, cheesy pus escaped from the sac. The preauricular glands were enlarged and there was a fistula at the left angle of the jaw. Tuberculosis and syphilis could be excluded but cultures from the pus showed the presence of the fungus known as *Nocardia*. The lesions set up by inoculation of guinea pigs closely resembled those caused by Koch's bacillus. Curettage and iodine locally effected a cure.—*La Presse Médicale*.

Miscellany.

Paris Hospitals in War Time.—Dr. Martinez Vargas, in several issues of *El Siglo Médico*, gives an account of a visit made by himself and sixteen medical colleagues to Paris last summer. The first visit after arrival in Paris was made to the sanitary service of the War Office, where the party was placed under the guidance of a medical staff officer, who first conducted them through medical Paris. The aim was to witness hospital activities, surgery, laboratory activities, the aeroplane service. The first week was spent in Paris and suburbs and the second at the front near Compiègne and Châlons-sur-Marne. The great military hospital at Val-de-Grace was the first building visited with especial reference to the new military museum, which had then (July, 1917) just completed the first year of its existence. All the archives and documents pertaining to the war are housed in this building, along with historical documents of the same character. In the museum proper all kinds of traumatism are reproduced in wax and as a counter exhibit wounds are seen in all stages of healing. Terrible mutilations are offset by representations of plastic work for their reintegration. Inanimate prosthesis vies with successful living grafts. Wax models and actual pathological specimens reinforce each other. Next to be mentioned is the x-ray department. From these exhibits which, of course, are not absolutely novel, one passes to others which are decidedly so and peculiar to the present war. Here are seen the latest types of projectiles, including explosive bombs of all kinds, gas apparatus, and masks stretchers and other apparatus designed especially for trench use, hence made collapsible apparatus for sterilizing dressings and purifying drinking water, etc. Every phase of war activity is shown in photographic or other reproduction. Trenches and communicating passages are shown by architectural drawings. The party next visited the Grand Palais. In 1900 Professor Vargas had assisted in the inauguration of this edifice at the exposition of that year. Now, there is an announcement to the effect that the work of the re-education of the mutilated is going on in this same structure. The contrast is a moving one. In one of the salons in the Palais had hung the paintings of Sorolla, the Spanish master, whose "Sad Heritages" had taken the prize of honor. Now these very halls have been divided and subdivided to form wards, operating cabinets, sterilizing rooms, etc. The great height of the ceilings made it necessary to remodel completely the interior of the edifice, so that nothing remains intact but the superb stairways. The wards for the wounded were visited, and Carrel's method of wound treatment was seen at first hand. Unfortunately for the party Carrel himself was then in the United States and they were unable to render to him the homage which was his due. In the hall of radiography they were told that 8,000 radiographs had already been taken and that the daily number was sometimes as high as 50 or 60. Dr. Mencièr's wards were next visited, where was to be seen a method which shares with that of Carrel the honors of French surgery. Mencièr, who

was fortunately present demonstrated to the Spaniards his so-called method of embalming the tissues. The liquid preparation applied to badly infected wounds, some with general sepsis, was shown to have the power of arresting and preventing decomposition and thereby of conserving the damaged tissues. In time was reached the department for physiotherapy and re-education. Mutilated men of all kinds, supplied when possible with prosthesis, were engaged in all kinds of activities. Many were learning the use of the left hand—an entire hall was devoted to these men—and blind soldiers were engaged in the massage rooms of the physiotherapeutic department. A superior type of men, former members of the liberal and artistic professions were selected for this work which extended to them the outlook for self-support. The rooms for mechanotherapy, thermotherapy, hydrotherapy, and electrotherapy were next inspected. The entire physiotherapeutic plant has had under its charge some 8,500 unfortunates in the past six months alone. The results have been splendid. Over 3,000 men have been completely rehabilitated and no less than 80 per cent. have returned to full military duty. Of the balance over half are equal to auxiliary work and only 7 per cent. are ineligible for army service in any form, although able to do clerical work. Professor Camus, who is in charge of the reeducation work estimates that from the beginning his department has restored to France the equivalent of 20,000,000 francs in income.

The visitors met Dr. Laborde, the distinguished woman who has charge of the radium department, where seeming miracles have been wrought. A cured case of sarcoma was seen in which a radium trochar had been plunged into the neoplasm; while numerous "before and after" photographs attested to other cures. Wax models, prosthetic apparatus, etc., formed the nucleus of a vast museum. The process of selecting men for the aviation corps was inspected. The electric chronometer of D'Arsonval was used for making the tests, which consisted largely of various reactions intended to bring out the exact state of the nervous centers. The dynamoergograph was used to measure the degree of fatigue after exertion. The school of instruction for aviators deals with many subjects of study calculated to atone for early defects of education when such exist.

The next visit made by the party was to the blind soldiers in the rue Reuilly. The asylum for these unfortunates is under the directorship of Dr. Emard. Much space is devoted by the author to the instruction of the blind in various occupations for self-support. The total number of the war-blinded in France is given as 3,000, which seems small in comparison with the popular belief. The annual pension for the blind soldier is 1,200 francs. Baskets were being made in great variety in one department—champagne baskets, market baskets, etc., etc. France used to buy all her basket ware from the Germans. In another department the manufacture of brushes was inspected. The labor of brushmaking is divided among a number of specialists, each of whom attends to a particular phase of the work. Such a

custom obtains in all manufacturing, but is of distinct advantage for the blind in mastering an occupation quickly. A relatively small number of men were making or mending shoes. Another industry for the blind was coopering, and still another iron work. In the latter occupation 25,000 detached parts of automobiles had been made. That nearly helpless subjects can be of such marked use in the great automobile industry greatly impressed the author. There was also press work done—not with types for the blind, but ordinary printing. Massage is barely mentioned by the author. By work along the specified lines the blind can earn 5, 6, even 8 francs daily—more, in fact, than most can earn who have their sight.

The party next visited the Val-de-Grace Hospital. The immense acreage of this institution makes it an easy matter to isolate contagious diseases of all kinds. This type of hospital apparently does not prevail in Spain and the party were impressed alike with the amount of air space, the absence of unsuitable and unhygienic architectural effects, the great shade trees, and and luxuriant flower beds. The first building visited was the typhoid pavilion. A narrow central hall gave entrance to large, light quadrangular wards, each with four to six beds well apart from one another, and a porcelain bath tub with hot and cold water faucets. The amount of space per patient, the free ventilation, the illumination, and the bathing facilities contrasted with the fact that at the time of the visit the typhoid pavilion had no patients, or rather of three patients in the six or eight wards none had frank typhoid. This lack of cases was a most eloquent tribute to the efficacy of antityphoid inoculation, which has practically suppressed the disease.

The next to be visited was the pavilion for tuberculosis. Isolation was assured here with no suggestion of quarantine. Both the family and personal history and the results of examinations were recorded with much thoroughness. If the patient had been a source of danger to his comrades word was sent to the front to disinfect his former habitation, on the supposition that "one consumptive makes a hundred others." The erysipelas pavilion was empty and it has been learned that an erysipelatos soldier always gets well of himself without treatment. Also vacant were the pavilions for measles and scarlet fever. On the other hand the mumps pavilion had been full of patients, many with complications. Professor Vincent, in charge of the manufacture of antityphoid vaccine, was found in a private pavilion, where an hour was passed. Numerous assistants of both sexes worked in silence among test tubes, flasks, and retorts.

The author next visited the Maison Blanche, now dedicated to wounded and mutilated soldiers and to those with mental disorders. The edifice proper, seated in extensive grounds, is surrounded by numerous temporary pavilions. One-half or more of the mutilated soldiers—those who have suffered amputation of the arms or legs—are or have been sheltered here until they could be fitted with artificial limbs and educated, if need be, to support themselves. One large pavilion serves as a warehouse for prosthetic apparatus. The visitor

is impressed with the lack of leather in the latter, but it has been learned that very thin sheet iron is superior for the purpose. Groups of mutilated individuals are testing the artificial limbs and the author experienced a sort of illusion of being in a large shoe store in which customers were being fitted to ordinary shoes. The men have their leg prosthesis fitted and then walk up and down to judge of its suitability. Various workshops, including a modeling room, were operated by mutilated soldiers. The enormous schoolroom was filled with men with artificial hands and arms and talented young women officiated as instructors. A husky youth was keeping a set of books in irreproachable handwriting, although it was something of a shock to see the wood and aluminum digits creep across the page while the pen was held in the proper position by spring power. Some who had lost the right hand were learning to write with the left and others even without an artificial hand were able to write beautifully with a special writing prosthesis fitted to the forearm stump. Men learn to fashion the separate parts of automobiles, or become draughtsmen, or take up other work of a sedentary character, especially when the loss of the lower limbs forbids an active existence. Lectures on various subjects helped to vary the monotony of existence.

An Arrow Poison Used by a Low Type of Brazilian Indian.—In the Pettersson's Festschrift number of the *Svenska Läkaresällskapets Handlingar* (Vol. XLIII) Santesson reports on a new arrow poison sent him by the well-known traveler Nordenskiöld, who began explorations in Brazil in 1913 and ascended the Madeira River and its affluent, the Rio Guapore, to a point close to the Bolivian frontier inhabited by the Huanyams, a very primitive Indian tribe who had but recently abandoned the stone hatchet. While not known to be cannibals they mutilated the corpses of their enemies to secure bone for arrow heads. They used in the chase both bow and arrows and blowpipe. The arrows shot by both blowpipe and bow are often poisoned with curare, but the species could not be ascertained nor the method of packing and storing. The poison is usually kept in calabashes, earthen pots, or bamboo tubes. The probability is that the *strychnos castelnea* weed grows in the Huanyam territory and supplies the poison. The arrow sent by the traveler presented an elongated head and the poison spread over it was wound over spirally with a thread. The length of the missile was 129 cm. and the poisoned head was protected with a cap of bamboo. A piece of bark which accompanied the specimen may have represented the source of the poison, for extracts of the bark, wood, and cord layer all showed a weak curare action on the frog. Microscopically these tissues appeared to belong to a member of the *Strychnos* family. Chemically the curare seemed to agree fairly with the calabash curare analyzed by Böhm. It dissolved to 77 per cent. in water, from which it was not precipitated by certain reagents and gave positive reactions with others. The toxic action on the frog and rabbit was typical of curare, the minimum fatal dose in the latter animal being 4 mgm. per kilo after subcutaneous injection.

Therapeutic Hints.

Remedy for Chilblains.—The following prescription gives relief of troublesome symptoms:

℞ Acid. sulphuric. aromat. 5 ij
Quinin. sulphat. gr. xxx
Tinct. ferri chloridi. 5 ij
Aquæ destill. q.s. ad. 5 iij

M. Sig.—To be applied two or three times daily, drying in the air before covering the parts.—*Medical Times*.

Headache.—In headache due to so-called rheumatic condition, Stevens offers this formula:

℞ Phenacetini
Salophen aa 5iiss
Ft. chartulæ No. xij.

M. Sig.—One every two or three hours.—*Manual of the Practice of Medicine*.

Bronchitis.—Stevens recommends the following in the subacute stage of this condition:

℞ Terebini
Olei santali. aa 15 ss
Strychninæ sulphatis gr. ¼
Codeinæ sulphatis gr. ij-ijj
Div. in capsulas No. xij.

M. Sig.—One every four hours.—*Manual of the Practice of Medicine*.

Cystitis.—

℞ Tinct. aconiti 5ij
Tinct. belladonnæ fol. 5i
Tinct. opii camphoratæ. 5ij
Spiritus ætheris nitrosi. 5j
Syrupi 5iv
Aquæ q.s. ad. 5vi

M. Sig.—Two teaspoonfuls in water every two hours, in acute cases with frequent micturition.

℞ Liq. potassii hydrox. 5ij
Fluidextracti uvæ ursi. 5iv
Tinct. hyoscyami 5iv
Tinct. lupulini 5iv
Tinct. opii camph. 5i
Syrupi zingiberis. q.s. ad. 5viiij

M. Sig.—Tablespoonful in water after meals and at bedtime, in chronic cystitis with acid urine.—THORNTON.

Acne.—The following is Kummerfeld's lotion:

℞ Pulveris camphoræ gr. x
Pulveris tragacanthæ gr. xx
Sulphuris præcipitati 5iv
Aquæ calcis
Aquæ rosæ. aa 5ij

M. Sig.—Apply every two or three hours.

Gout.—

℞ Magnesiæ 5ij
Magnesii sulphatis 5i
Vini colchici corni. 5i
Aquæ menthæ piperitis. q.s. ad. 5xii

M. Sig.—A tablespoonful every hour for four or five doses or until the bowels are freely opened.—SCUDAMORE.

Menorrhagia.—

℞ Fluidext. ipecac
Fluidext. digitalis. aa 5ij
Fluidext. ergotæ q.s. ad. 5j

M. Sig.—Thirty drops every two hours until relief is obtained or extreme nausea occurs.—BARTHOLOW.

THE PROBLEM OF TUBERCULOSIS IN MODERN ARMIES AT WAR, AND ITS STUDY AND SOLUTION IN THE ITALIAN ARMY.*

BY ATTILIO MARIO CACCINI, M.D.,

MAJOR, M. R. C., U. S. A.

NEW YORK.

VISITING PHYSICIAN OF THE HOSPITALS OF ROME; INSTRUCTOR OF MEDICINE IN THE ROYAL UNIVERSITY OF ROME; ATTENDING PHYSICIAN CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK CITY; CHIEF OF BUREAU OF BIOLOGICAL SCIENCES AND PREVENTIVE DISEASES, INTERNATIONAL HEALTH BOARD OF TURKEY-IN-ASIA; SUPERVISING PHYSICIAN OF TUBERCULOSIS CLINICS, HEALTH DEPARTMENT, NEW YORK CITY.

AMONG the various complex and important questions that the war has created none has assumed greater prominence than that of tuberculosis. In such a war as the present the army presents vastly different aspects than those observed under peace conditions. Then it represented the best the nation possessed of healthy youth, carefully selected, rigorously examined, and adequately guarded against the possible infiltration and spread of disease. Now, however, armies are composed of men who have been enlisted after an examination which is, of necessity, less methodical and accurate than that which formerly obtained. In addition there are the hardships that are inevitably attendant upon military operations and which multiply the causes of all diseases. This is particularly true of tuberculosis.

It was the purpose of the Italian military authorities to achieve a diminution of the high percentage of tuberculous individuals, and in connection with that purpose arose two important points that demanded solution. One was the prevention of enlisting men who presented specified and active manifestations of the disease; the other was the elimination as soon as possible of the prime sources of infection—the men who developed active symptoms during the period of their service.

This problem had received considerable attention in medico-military circles for some time, and with the mobilization of the Italian troops it reached an acute stage. Indeed, as soon as mobilization had begun and soon after active hostilities were inaugurated, the problem grew to such proportions that there was recognized the immediate necessity of organizing a special service to deal with it in accordance with modern views on tuberculosis.

From every corner the War Office received warning of the danger of retaining in the military service tuberculous subjects who had been accepted as

*Published by permission of the Surgeon General, U. S. A.

physically sound. Such a situation could develop with no great difficulty—probably during one of those periods of disappearance or latency of the active phenomena, for it frequently occurs that subjects who are passing through one of those periods of rest in the progress of the disease are admitted into the army. There they are exposed to conditions coincident with military life that diminish their general resistance, under which they easily lose that negative health which they had enjoyed as civilians and might have continued so to do for the rest of their life. Moreover, there was the economic side of the question to consider. When a man develops some form of tuberculosis after he has entered the army he must, of course, be discharged as soon as that condition has been discovered. This has always been done, and in almost every instance the question of the responsibility of the military authorities has arisen in connection with the inevitable issue of the liquidation of pensions to the discharged man or his dependents.

It is the opinion of the majority that the government must bear the responsibility of every case of tuberculosis that develops in the army, arguing that a recruit must be recognized as free from tuberculosis upon enlistment by the mere fact that he had been accepted at such time. This argument, of course, is not scientifically accurate, for it admits no discussion of the possibility of diagnosing the disease at the time of the medical examination of the recruit.

It is clear that by such an assumption the tuberculous patients are placed in a favored position in comparison with victims of other diseases. But then we must not forget the seriousness of awakening the tuberculous process as compared with any other disease whose activity may be stimulated by the army life; nor must we forget the more serious effect on the community of any case of tuberculosis and the more diffusive types of the disease.

The Italian medico-military authorities decided that until new methods permitted the positive discrimination between the healthy and the unhealthy recruit, the only practical way was to increase the severity of the medical examinations. At the same time it was considered necessary, practical, and humane to make provision for those subjects who had been enlisted while they had lesions or localization of foci that could or might awaken under conditions of military life.

As a result we have the "Reparti di Accertamento Diagnostico" (Diagnostic Centers) for the rapid and correct identification of tuberculous lesions, and the "Centri Sanatoriali" (Sanatorial Centers) for the cases of initial tuberculosis whose discharge from the army had been left undecided.

In this way an opportunity was given the military authorities, with their almost unlimited means, to provide for the treatment of all those cases that might possibly be considered susceptible of recovery. This meant the application of a more modern view in the diagnosis of tuberculosis.

The proper operation of these centers was regulated and controlled by the issuance of a series of Special Orders.* The first circular, No. 801, December 29, 1916, institutes, regulates, and disciplines the new service. It is integrally reproduced as follows:

"The Prophylaxis of Tuberculosis in the Army.—

In the territory of each army corps there shall be established special hospitals for diagnostic purposes for the prompt and accurate identification of tuberculous lesions or of such lesions as are under suspicion of being tuberculous in character. These hospitals shall be established in localities separated from other hospital buildings, civilian or military, and shall be placed in rural regions where possible. They shall be provided with all necessary means for an early, prompt, and positive diagnosis, including conveniences for bacteriological research.

"The personnel for these hospitals shall be selected from among those medical officers who possess special competence in the subject. They shall have the assistance of a special staff carefully instructed in the treatment of tuberculous patients. There shall be sent to these hospitals: (1) Any recruit who is found to be affected by incipient, latent, or dormant forms of tuberculous infection at the time of his physical examination. These forms include cured lesions of the bone, relics of glandular lesions, sequelæ of pleurisy, etc., with special regard for localizations of the respiratory apparatus. (2) Any enlisted man who may show signs of the lesions mentioned in paragraph 1.

"The medical officers of each organization shall cause all those men who show a general as well as a local condition (authorizing the suspicion of a latent tuberculous lesion) to be subjected to a special clinical observation. Upon the completion of the period of necessary observation for properly ascertaining the suspect's condition, those who shall have been proven affected by the active tuberculous infection shall be declared permanently unfit for military service and shall be discharged from the army. Proper notification shall be sent to the civil authorities of their place of residence. The recruits who are found affected by forms recently healed shall be declared temporarily disabled and shall be sent home to await future calls to the colors. At the time of the physical examination those men who appear affected by active tuberculosis to the extent of offering small hope of recovery (such as diffuse, cavitary, or forms of rapid evolution) shall be immediately discharged and the civilian authorities shall be promptly notified so that they may be in a position to take the necessary measures of social and individual prophylaxis.

"Those who are found affected by incipient forms of pulmonary tuberculosis or any such form that may give promise of improvement under treat-

ment (or at least arrest of progress) shall be transferred upon the advice of the executives of the Observation Hospital (from which they have been received) to the Sanatorial Centers which have been previously established. These Sanatoria are to be recognized and authorized by the Military Administration with the proper act of the Ministry of War, and will be placed under the technical control of the Local Sanitary Board of the Army Corps of the territory in which they are located. They shall also be placed under the administrative power of the Local Sanitary Committees.

"The relations between the Military Administration and the civilian authorities controlling the locality identical with that of the Sanatorial Center shall be, as a rule, governed by the following regulations: The Corporations under which the Sanatorial establishments exist will assume the following obligations: (1) To accept and maintain all of the military that are affected by pulmonary tuberculosis who may be sent there directly from the Diagnostic Centers of the Army Corps. (2) To provide at their own expense for the buildings and for their upkeep. (3) To provide bedding and all necessary hospital furniture and maintenance thereof. (4) To provide suitable subsistence and all drugs and surgical necessities for inmates. (5) To provide the medical personnel, nurses, and civilian employees, etc.

"The Principal Military Hospitals shall make provision for each Sanatorium in accordance with proper and accustomed usage as follows: (A) The daily rations and expenses for each soldier and the regulation allowances due him upon presentation of the proper voucher in accordance with the same rules which apply to the military in civilian hospitals as directed by Article No. 710-11-12, etc. (See Manual of Military Administration.) (B) The period of treatment in the Sanatorial Centers shall not be less than of four months' duration; it may be prolonged by two months more upon advice of the physicians in charge of the Sanatorium through the local military authorities, but such an extension shall apply only to such patients who have shown notable improvement.

"Upon the expiration of the four or six months' period the proper medicolegal steps shall be taken at the Diagnostic Center of the Army Corps for every individual case, and each case shall be judged on its merits. If the tuberculous infection is still observed as active (although improved) the soldier shall be discharged and the proper civilian authorities notified of the case. If a cure is effected the soldier shall be sent to his Regimental Depot for sedentary service only.

"When a recruit is rejected from the service because of tuberculosis conclamata the hospitals or the Diagnostic centers certifying the rejection shall notify the local civil authorities.

"(Signed) The Secretary of War."

Circular 1501/56 confirms the principle that the Diagnostic Centers are to be maintained only for an early diagnosis while the Sanatorial Centers are established for *treatment*. It insists that the medical personnel consist only of men particularly capable in this work, and that each institution must be provided with all necessary means for an early diagnosis and subsequent treatment.

*Special Order No. 801, Dec. 29, 1916; 1501/56, Jan. 6, 1917; 1503/56, Feb. 26, 1917; 1504/56, Mar. 13, 1917; 1563/56, April 26, 1917; 333, May 17, 1917; 300924, July 6, 1917; 302198, Aug. 27, 1917.

The other circulars discipline and regulate the movement of patients, emphasizing the necessity of excluding from the Sanatoria all cases that are in an advanced stage. The medical officers are enjoined to keep under close observation all such patients in their organization who are known to come from families where there have been or are at present open cases of pulmonary tuberculosis, and to observe those who were found to be delicate or with suspicious thoracic characteristics at the time of the initial physical examination. The final circular enjoins all officers to notify the Prefect of the different prefectures of each pertaining case discharged from the service on account of the disease, so that a proper observation may be maintained.

Now let us consider our subject in a more general way. Let us endeavor to place in their correct relationship the waging of war and the progress of tuberculosis. With the formation of our vast present-day armies this subject has been brought into greater prominence than ever before. As a result, the laity and a great many physicians have come to the conclusion that war increases the morbidity of the disease. But this is a point that requires an explanation. There is no doubt that there is more tuberculosis now than there was before the war, but it is true that the number of actual infections brought about by the war itself is infinitesimal. Practically the same thing has happened to the enlisted man that happens to the immigrant in the large American industrial centers. The changed conditions of living, the overwork, the poor sanitary conditions of the tenements and shanties of mining districts—all these elements, together with the alcoholism and dietetic errors awaken the latent disease in the European peasant by considerably lowering his powers of resistance.

The conditions incident to the war similarly diminish the powers of resistance of the enlisted man, and many individuals who, under the civilian regime, would not have developed the disease have merely anticipated the manifestations of it. Others who perhaps might never have given evidences of a tuberculous state have developed active symptoms when they might have gone through life with simply a latent infection.

One can consequently state positively that *the war has not created new tuberculous cases*, but that *it has increased the rate of the disease* by anticipating or stimulating the manifestations of the tuberculous process in individuals previously clinically healthy.

And when one considers that the army is composed of the youngest and presumably healthiest part of the adult male population, the urgency of the solution of this problem must be recognized by every enlightened State. Particularly is this the case when it is remembered that the Administration is provided with a valuable guide in its endeavors; for every rejected recruit furnishes an index or gauge for each relative family, and as such supplies the means of indicating a probable center of infection. Thus it is that from the military administration, as fruit of the war, may come the best means of visualizing the national problem of tuberculosis in all its aspects.

It may be easily understood that to carry on a work of such tremendous importance—where na-

tional safety is so closely allied with the personal, human element—the pioneer must possess a steel nerve; that he must be endowed with qualities that include the moral courage of facing the issue squarely; that he shall dismiss from his mind all prejudices—moral, economical, technical. And here it may be emphasized that the prejudices that exist in the medical mind are perhaps more numerous and more pernicious, frequently providing the greatest obstacle to the happy solution of the problem. In fact it is from his colleagues that the pioneer in this great work must expect the greatest opposition.

What is true of the world at large was found to be equally true in Italy. Any movement that is essentially the product of *modern* thought, if it is to be successful, must be strengthened not only with the individual courage of the adventurers, but by system and procedure that in itself will excite admiration. It is perhaps with a realization of that truth that the Italian War Ministry established the Diagnostic Centers—one of the admirably strong premises in its admirably strong proposition. Let us examine, then, the actual operation of this first link in the chain.

The Diagnostic Center is really an observation hospital under the direction of a staff of especially competent diagnosticians in tuberculosis. It is equipped with the most recent and modern requirements for such work. It is, as has been pointed out, the headquarters for the territory of its relative Army Corps to which must be sent all recruits having a tuberculous history or the appearance of the relics of conditions which are suspicious in this connection. The suspect is retained there only for such time as may be necessary for the completion of the requisite diagnostic observation. Thereafter he is subjected to the proper measures that his case may demand—leave of absence, sanatorial treatment, or actual discharge. If the condition of the suspected recruit justifies his discharge the Prefect of the province from which he comes is notified. This is an important point, for instead of being merely rejected from the army for reasons of physical unfitness and allowed to return to the ordinary pursuits of civil life, the man is practically invalidated home and becomes, in effect, an out-patient of a national hospital system, and is amenable to the control of the provincial authorities who will keep him under observation, taking such measures as may be deemed necessary to protect the public and place a check upon this one possible source of infection. These measures may include the improvement or removal of those conditions (social or otherwise) that may stand in the way of recovery.

The work of the Diagnostic Center may be viewed from three important angles: statistical, technical, and sociological.

As a medium for obtaining statistics in connection with the disease, the plan is unrivaled. It at once places in the category of tuberculous subjects those men who might never have been recognized as such under civilian conditions (with the attendant dangers of those circumstances) or those who might have evaded observation because of their social status. But the military service is a leveler of class, and this fact assures the sincerity of the investigation, since through the Diagnostic Center must pass the poor and wealthy, the professional

man and the laborer. The Center provides a fountain of statistical information unequaled in any civilized country and which has been approached, in quantity, by no other modern institution. It establishes a rational base for the war on tuberculosis that society must wage in the future.

FIG. 1.—General View of the Diagnostic Center.

The technical aspect is not at once susceptible of appreciation because it is comprehensible only to those of the medical profession. And even in this connection one may easily be guilty of a syllogistic fallacy. For real appreciation of the work of the Diagnostic Center will be found only among those of the profession who are profoundly interested in the movement, maintaining no prejudices, and striving to achieve a modern viewpoint of the subject.

The sociological aspect is most profound and is progressively important with every development of tuberculosis pathology. But it is chiefly notable in its ability to form a solid and practical contact with all civilian activities that protect the public from the further diffusion of the plague. The importance of it is sufficiently demonstrated by the procedure employed in the method of dealing with the cases discharged from the army; that is, advising the proper civilian authorities under whose jurisdiction the discharged case will fall. It is a remarkable fact that while some of the old Italian States, as far back as the eleventh century, provided for the registration of all cases of tuberculosis, modern public opinion in Italy had erected innumerable barriers in the way of such beneficial regulation. A strong prejudice existed against the system, on the ground that it was oppressive and inhumane. However, by means of the order which established the Diagnostic Centers, the registration (or more properly, the notification of civilian authorities) became a *fait accompli* throughout the country. It promptly terminated all manner of discussion, scientific and otherwise, which had from time immemorial suspended the actual application of the ancient provision. In other words, a moribund law was brought to life.

The benefits of this system become at once apparent, for under the operation of the present procedure the man discharged from the army is automatically placed in the hands of the proper civilian authorities, and regardless of the social stratum in which he may belong his case may be followed up by a series of investigations which will have for its finality not only a remedy for the individual

but also one for the community. When a recruit is rejected it is not unreasonable to suppose that other cases exist in his immediate family. Thus he has provided an index which can now be used in community work.

Investigations have, of course, been conducted by different local institutions—dispensaries, hospitals, sanatoriums, health boards, etc.—but they have hitherto been limited in their scope, and at their best are of a fragmentary nature; they have been insufficiently coordinated, and never used as a national unit for collective defense against the spread of the disease. Under the new dispensation, however, the government possesses the power to effect the necessary coordination by creating a working organization polarizing all findings toward one point.

And now let us observe the performance of the Diagnostic Centers, and such observation must include not only the details of the methods of handling the material (men) but also the plant and apparatus employed.

For an illustration, the Center situated in Rome will serve admirably. This is under the direction of Dr. N. Sforza, one of the best and most progressive minds in the capital. This Center occupies two pavilions adjoining the Hospital Umberto I.* Its location is a logical one, since that hospital is dedicated to the exclusive treatment of tuberculous cases in Rome. The two pavilions erected for the use of the Center are of the same general construction as that of the hospital, although they are entirely isolated therefrom, being surrounded by spacious gardens, which are in turn strongly fenced against promiscuous ingress or egress. Indeed, in so far as the pavilions themselves are concerned, they are absolutely independent of the older organization. The two buildings are connected by bridges on either floor, which are used as sun parlors, protected at will by awnings. There the patients may enjoy the air and receive eliotherapeutic treatment. There is also a completely equipped bacteriological laboratory for use in connection with any pathological findings. In addition there is a radiological laboratory provided with all the necessary apparatus for x-ray work. These two pavil-

FIG. 2.—Gateway to the grounds of the Diagnostic Center.

ions form the center of observation for the Roman territory of the Army Corps.

*See July, 1911, number of *Out of Door Life*, issued by the Nat. Ass. for the Study and Prevention of Tuberculosis.

It has been found that the average time required to reach an accurate diagnosis is ten days. The necessary investigations include a general clinical observation (temperature, functional disturbances, etc.) and a physical examination of the respiratory apparatus. There is also noted the cutireaction to

FIG. 3.—Garden between the two pavilions.

tuberculin, and also radiological, laryngoscopic, and bacteriological examinations. From the data thus obtained the clinical record is made which contains the diagnostic decision. A thoroughly adequate system of statistics is maintained in the office concerning the entrance, exit, medicolegal decisions, and destination of the patient.

A complete and exhaustive radiological archive was established where all films and prints are kept. The photograph has found preference over the radioscopic examination for the obvious reason of its greater precision in the examination, and also as a necessity of record. This archive provides rich material for further study of the disease.

The Diagnostic Center of the Army Corps of Rome has a mean daily movement of twenty patients.

One who has studied the operation of such a Diagnostic Center cannot but marvel at the diffusion of the disease—a diffusion far beyond the expectation of even the very men who have for years past been in intimate contact with the problem. Such impressive findings are hardly alleviated by the slight consolation that may be derived from the very facts themselves; that is, that the more there are of the cases of diagnosed tuberculosis, the pessimistic significance of the disease is actually diminished by the percentage value of it in relation to mortality. Death from tuberculosis is comparatively rare among the great number of diagnosed cases. But the disease is none the less insidious; indeed, may it not be said that because of its very insidiousness it is the arch foe of the medical profession?

The medical officer on duty in these Diagnostic Centers throughout Italy is chosen with great care. It must be borne in mind that he is a physician who must, from his scientific premises, come to practical conclusions, limited and therefore consequential. His diagnoses have tremendous possibilities. No theoretical comforts may relieve his mind when he is confronted with the enormous number of discharges from the army that he must continually make. He is serving the State, he is serving so-

ciety; but does it not require a mind of broad vision to behold that, when at the same time he is, perforce, depriving the State and society of men to defend it? For when a physician is convinced that an enlisted man is unquestionably tuberculous he must discharge that man from the army, notwithstanding the adverse criticism that may come from any quarter. Naturally, one would look for such criticisms in circles that are purely military, but indeed, they come even, or it might be said *particularly*, from professional quarters. One must not forget that the real obstacles in the solution of the tuberculosis question have never come from the laity but from the medical profession itself. It is there that we find the real prejudices against proper diagnosis and treatment of the disease, prejudices that are most active, almost unbelievable, almost beyond remedy.

In medical circles one will frequently hear discussion of latent or dead foci of tuberculosis, of inactive forms, of periods of quiescence of the disease, etc. But physicians are loath to recognize all that when diagnosing a particular case. The worst of it all is that these forms do truly and actually exist; that they do truly and accurately reflect actual and biological clinical forms. Any physician who intelligently maintains a contact with the disease knows this well, and knows quite as well within what reasonable limits they can be traduced into actual clinical realities, authorizing prognostic hopes—even guides to therapeutic tentatives.

It is of supreme importance that prejudices such as noted above should not be allowed to influence a work of such universal necessity as presented by the Diagnostic Centers. If these prejudices were permitted, and a man was diagnosed as free from disease when he was only passing through a period of its latency, then surely the operation of the system would be rendered useless.

In the consideration of tuberculosis we must not forget the aphorism that it is not a disease with an obligato feature. Tuberculosis is a disease that accompanies the patient to the end. He may defend himself against it more or less successfully during certain periods of his life; the disease may show

FIG. 4.—The south front of the Diagnostic Center.

itself in many aspects, but this is only a question of actions and reactions. They may or may not be susceptible of clinical observation without the potential and unsuppressible truth (the infection) having been contradicted or confirmed by appearances.

In other words, he who has once been the recipient of the infection, or has carried for some time the clinical manifestations of the disease, will never be free from the possibility of showing other signs to-morrow, even under the most favorable circumstances of living.

FIG. 5.—Balconies of one of the pavilions.

Consequently, it must be considered as a very serious professional error to say that a subject *has been* tuberculous once. A man *is* or *is not* tuberculous.

Owing to the strict application of this principle one of the most rigid measures introduced in the Italian army has been the absolute refusal at the initial physical examination of all men who had a history (naturally easily confirmed by other findings) of a past pleurisy. This resulted in the introduction into the list of causes for the rejection of candidates of "relics of pleurisy" when clinically ascertained. These comprehended interlobitis and sclerosis, no matter how partial or limited. *Ex ungue leonem*; where there is the sign there is the danger always. The only remedy, the only preventive measure in any such case is the rejection of the candidate, or, if discovered after his enlistment, his discharge forthwith.

It was thought at first that such individuals might be used for such light or sedentary services as there are in the army. But the error of that idea promptly manifested itself. The Military Administration derives little advantage, if any, in retaining men who can give only a minimum of service, and who are continually threatened by possible recrudescences or by new manifestations. Their mental condition is also bound to be abnormal. They inevitably become self-conscious, a state brought about by the nature of the assignment itself. And since illness does not necessarily beget virtue, a man officially pronounced invalided would be pretty sure to take advantage of such a situation. We cannot conceive of a soldier who is only partly healthy. To recognize such partial invalidism and still oblige him to serve, under circumstances that might aggravate his condition, is a plain antithesis, especially when that invalidism is caused by tuberculosis. Hence it is only under certain circumstances that a government could consent to the partial utilization of invalided men. France, for instance, provides an illustration of the stern necessity of using all of the national energies susceptible of any one military value. Fortunately, in Italy, the

material *man* is not so scarce. This question, which is still an open one among the medical journals of France—that is, as to if, how, and why invalided men may be used—may still be considered a fine point of medical ethics, and is only of academic interest in a country like Italy, where the prime material is far more abundant. Here it may be said (and very often is) that a tuberculous subject frequently experiences conditions of equally intense activity in civil life that he would find in the army, but the answer to that is that the spontaneous nature of the work imposed by military necessity is far more onerous, and is at all times compulsory. A man in the army, whatever his rank, can hardly be considered as a free agent. Moreover, the government has an administrative responsibility that demands the complete protection of the community. And as we are discussing that responsibility in relation to the campaign of prevention of a widespread disease, no matter what partial use may be made of an invalided soldier, no other diagnosis could possibly be substituted for the one pronounced at the Center for tuberculous diagnosis.

The foregoing facts argue definitely against the wisdom of retaining the services of a man invalided by tuberculosis. An accurate diagnosis once achieved, there can be but one proper course—the man *must* be discharged from the service.

Another phase which may be discussed is the

FIG. 6.—Sun gallery of one of the pavilions.

serious and delicate technical question of *suspect* cases. Herein appears the ability of the examining physician and the opportunity for exhibiting that rare sense called common, together with the courage to confront all difficulties and prejudices of public

opinion, both lay and medical. The list of customary causes for discharge from the army include, among numerous others, such conditions as oligemia and organic impoverishment. Those, of course, roughly cover tuberculous subjects. But do they provide for

FIG. 7.—Interior of one of the pavilions.

dealing with suspect cases? Hitherto it would seem not. The question of suspects may even be considered a superfluity from the medical point of view; from the medicolegal, as artificial. It is susceptible neither of limitations nor of distinctions. It oscillates between two extremely variable quantities—the patient, with all his varieties of reactions, consistent with the conditions existing when he comes under observation, and the examining physician, with his intellectual qualifications and the means of investigation at his disposal. Consequently, there is absolutely no logical basis on which to rest the arguments concerning investigation that are, unfortunately, so frequently indulged in at present.

One of the characteristics of the scientific mind is the tendency to create postulates of a static disposition out of certain conceptions which are essentially dynamic and in a continuous movement. Thus may be explained the difference of interpretation between those who have mastered the secrets of accurately interpreting radiographical plates and those who possess only an indirect and academic (or theoretical) knowledge of the subject. The mental orientation is deeply influenced by this tendency.

The problem of an early diagnosis of the elements of relativity is a complex one, and it must consequently be considered and interpreted with proper consideration of the most extreme and practical possibilities of its constituting elements. By the term *early diagnosis* and its concurrent problem it must be understood that it is considered as a clinical and not as a biological problem. Nevertheless, it is recognized that a biological reaction can be fairly well employed for the early diagnosis, such as the various tuberculin reactions, and especially the reactions of particular foci. But in so far as it is employed it presents to the observer a clinical fact on the level of a suspected or unsuspected lesion; otherwise it would be void of any practical value. The cutireaction, for instance, is void of any such value, because it detects the *infected individual* and not the *sick person* (a conception one must never forget in practical work) and it is consequently unavailable as a criterion of judgment.

Here it may be said, incidentally, that the Diagnostic Centers have not used tuberculin for diagnostic purposes, inasmuch as its use is attended by certain dangers that cannot be conveniently studied and controlled in such centers where the presence of the patient is of brief duration. Moreover, there are other *passive* means which are quite harmless. Again, it is not necessary to determine whether the foci are active or not, since, as has been said before, the discovery of a tuberculous focus in itself carries with it but one conclusion—the dismissal of the soldier from the service.

Hence, instead of tuberculin injections, the radiological examination is used at the Diagnostic Centers. The value of the conclusion that may be derived from the x-ray examination for the purpose of diagnosis in pulmonary tuberculosis is still an unknown quantity with most physicians, even among those who may be termed quasi-expert. That may not be true, perhaps, concerning their technique, but the employment of the radiological examination demands that the investigator be possessed of special and highly developed qualifications if he is to detect certain aspects of the disease which the other diagnostic means reveal much too late, if, indeed, at all. Technique, of course, is a necessity, but it is even more a matter of habit and experience of observation. Naturally, very few physicians have the opportunity to examine enough x-ray photographs and films to enable them to read them well and accurately, a difficulty of no inconsiderable importance in itself. Consequently, misinterpretation has not been uncommon, and has justified the lack of confidence of many of the profession when confronted with those who affirm that radiology can solve many clinical problems in tuberculosis; that it can discover *new* problems. Furthermore, those expert radiologists declare that it is a valuable aid in the rendering of an early diagnosis, and where accuracy is desired (and where is it not?) it is at all times indispensable. But it is only a matter of time when this relative ignorance within the profession will disappear, for it must be remembered that we are barely past the elementary stages of our research in this connection.

FIG. 8.—The radiological laboratory.

There are many physicians who believe that a simple radiological examination of the chest is sufficient for an accurate diagnosis. That is a mistaken idea for reasons both technical and essentially human. Among the former is the inability of the

radiograph to reveal certain lesions such as a fine sclerosis, peribronchitis, partial pleuritic thickening, some sort of interlobitis, etc.; in short, all those minute lesions that one may merely suspect at a clinical examination, and that only a repeated set of photographs can demonstrate definitely. In the latter, the human reason, we have the nature of the disease itself. We must always be ready to prove to-morrow (and this to-morrow may be after many years) that a certain fine lesion existed, and this even when the patient cannot be photographed anew. We must not forget those periods of rest that take place in the progress of the disease and that may *camouflage* any kind of tuberculous lesion. Nor must we forget human nature and those many human prejudices which make progress difficult. If we have the photograph, all doubt, all arguments, all waste of time caused by argumentation (which an expert may know to be useless, but which must, nevertheless, be met and answered, particularly when advanced by influential or so-called authoritative colleagues), all these fall away and the facts stand out by themselves in the photographed evidence.

There is another reason, also. Reading a film made with such fine technique that it will show the most minute differences in the pulmonary tissue is a different matter from reading one produced with that technique that shows only a certain few aspects of the tissues; just as it is not the same reading that results from the interpretation of identical microscopical preparations when examined with two different systems of lenses with two different diameters.

Furthermore, it must be remembered that the x-ray photograph is not always capable of solving the question of the diagnosis of pulmonary tuberculosis. It is only a great help in many initial cases. Other means are often necessary. Of course, we must here exclude the chemical and the bacteriological examination of the sputum as a good means of diagnosis. That belongs to a primitive age, so to speak. He who expects to make an early diagnosis based on an examination of the sputum (even though conducted with the best and finest of technique) may be considered a dangerous physician. And in regard to this point we find ourselves unfortunately confronted with a medical mentality that must be entirely renewed; the technical medical education reflects the effects of that great human law that makes our minds susceptible to that inertia which our mentality seems to possess in relation to all scientific discoveries.

Another observation that is surely of importance in achieving an early diagnosis is the thermometric. Yet its value may very easily be overemphasized, particularly when applied in connection with the Diagnostic Centers of our discussion. If thermometric observation is to be at all useful, the temperature of the patient should be taken frequently (oral or rectal only) in relation to the different periods of the day, often after proof of fatigue or muscular exertion. And here the ever-present human element appears, with the inexperienced personnel on one hand, and on the other the types of patients under observation: the rowdy, the diffident, the insincere. The experiences of the Diagnostic Centers prove that the thermometric observation

under such circumstances is at least of small value.

One of the valuable discoveries of the Centers has been the importance of the laryngological examination, revealing clinically at an early stage the existence of a process yet latent in the rest of the body. This examination has now been established as a routine procedure, and the helpful data acquired with its assistance are almost astounding. Many forms of infiltration lacking the characteristics given as peculiar to tuberculous infiltration (paresis of the vocal chords) have been discovered in individuals who presented only a slight bronchial adenopathy or some other slight and uncertain tuberculous stigmata. The assistance of such findings has been considerable since it has provided the opportunity for confirming a diagnosis of a very delicate clinical character; further, it has served as a decisive factor in making such a diagnosis. Cases have often been kept under observation where the suspicion was strong, but the mind was still doubtful, and it was due to the confirming revelations of the laryngological examination that the end in view was achieved, which in our present discussion is the discharge from the army. Subsequent clinical facts that the patient revealed plainly confirmed the diagnosis. In fact, the conclusions developed by the aid of this particular means of diagnosis have been such that we can hesitate no longer in declaring that the results obtainable from the systematic examination of the larynx are quite as important (and often more so) than the results of any other means of examination and of diagnosis. Frequently it is only with this examination that the presence of the disease may be even suspected.

We have said before that a definite diagnosis is only achieved by the proper coordination, the contrast, the interpretation, and the criticism of the various elements gathered through the different diagnostic investigations. We must remember the nature of the Diagnostic Centers and the finality of their findings; the diagnoses pronounced there have a complex and ultra-individual finality. The early diagnosis of tuberculosis, then, must be considered from this limited point of view.

As a result we have a true *military diagnosis of tuberculosis*, and this theory, first expressed by Maragliano, is neither artificial nor sensational, but really corresponds to an actual reality. The medicolegal valuation of the military surgeon involves the responsibility of the physician, the future of the patient, and the fiscal and administrative responsibility of the government. To appreciate that, and demonstrate it practically, is a very difficult thing to do, and causes many errors, either in excess or in defect. But under the present system the elements of the objective conditions are all gathered into two great categories by the experienced authorities in the Italian service.

These are (A) Criteria of Certainty and (B) Criteria of Presumption. These may be examined in detail as follows:

A. Criteria of Certainty for a Definite Diagnosis.

1. When the result of the examination reveals the presence of the tubercle bacillus.
2. When there is a positive laryngeal localization.

3. (a) When the result of the examination of the sputum is negative, *but* (b) the radiological examination is positive, beginning with the pictures of bronchopneumonia and pleurisy, and followed to their respective possible conclusions, *even when* (c) the stethoscopic examination is negative.
4. (a) When the examination of the sputum is negative, *but* (b) the radiological examination is positive (see 3 b) and (c) the stethoscopic examination is positive.

With these formulæ it would appear that all varieties of tuberculosis can be classified, including the latent forms (3) and the laryngeal (4 c). The term *negative stethoscopical examination* signifies the absence of pathological alteration of the respiration, in the same manner as the opposite is meant by the *positive* stethoscopical examination. It is clear that they should not be assumed as decisive unless confronted and confirmed by the radiological findings.

No diagnostic certainty (that is, the discharge of the soldier) is attributed to the radiological examination unless there is found (2) bronchopulmonary or pleuritic lesions, and not to adenitis or peribronchitis only.

The formulæ of Criteria of Certainty may be outlined as follows:

- I. Examination of the sputum, positive.
- II. Laryngological examination, positive.
- III. Examination of the sputum, negative.
Radiological examination, positive.
Stethoscopical examination, negative.
- IV. Examination of the sputum, negative.
Radiological examination, positive.
Stethoscopical examination, positive.

In the valuation of the Criteria of Presumption we must be even more cautious, but proceeding from the simple to the complex, from that which is easy to that which is difficult, the following conditions provide adequate expressions. It must be remembered that these criteria are made the subject of suspect cases.

B. Criteria of Presumption for a Definite Diagnosis

1. (a) When the examination of the sputum is negative *but* (b) while the stethoscopical examination is negative, (c) the radiological examination (from the type of the bronchopneumonia and of the pleurisy on to their respective possible conclusions) (as in A 3b) is positive (including adenitis and peribronchitis), and (d) the symptoms of general infection are present.
2. (a) When the examination of the sputum is negative, *but* (b) the stethoscopical examination is positive and (c) the radiological examination is positive, although (d) the general signs of infection are absent.
3. (a) When the examination of the sputum is negative, *but* (b) while the stethoscopical examination is negative (c) the radiological examination is positive, although (d) the general signs of the infection are absent.

Outlining the formulæ of Criteria of Presumption, we have the following:

- I. Examination of the sputum, negative.
Stethoscopical examination, negative.
Radiological examination, positive.
General symptoms, positive.
- II. Examination of the sputum, negative.
Stethoscopical examination, positive.
Radiological examination, positive.
General symptoms, negative.
- III. Examination of the sputum, negative.
Stethoscopical examination, negative.
Radiological examination, positive.
General symptoms, negative.

These formulæ are not artificial creations, but rather a tentative reproduction of the most common varieties of clinical conditions in which the individual cases come under the observation of the military surgeon. They must not be construed as clinical definitions of the morbid varieties of the infection, but as *orientations of the criteria* which seem justifiable, and which can well be used in practice by tuberculosis specialists.

From the military point of view the realization of criteria of certainty naturally imposes upon the examining physician the duty of discharging the patient from the army, while the realization *only* of the criteria of presumption will render him uncertain as to his course, an uncertainty that will oscillate from a maximum to a minimum. In the first instance, a leave of absence is granted. These leaves may be for four, six, nine, or twelve months, postponing definite judgment to later observation. At the end of the furlough the soldier will return—not to his regiment, but to the Diagnostic Center which has pronounced the diagnosis or judgment on the case. This provision allows the physician again to examine the patient during another period of the disease, thus making use of elements that the case did not possess at the time of the first examination. It also guarantees to the soldier the advantage of being again examined by the same physicians who have pronounced the first diagnosis, and who now have all the additional data which may have been made evident, and which may have come within the range of observation. In this way a definite decision may be achieved. The operation of this system of furloughs has encouraged its use. If it should occur that presumptive criteria are almost lacking, the soldier is detailed to sedentary service.

In the zone of military operation there have been provided local Diagnostic Centers for those men who show signs of tuberculous infection. These Centers are a part of the local base hospitals, but are thoroughly isolated therefrom. Their structural arrangement is uniform throughout the army.

Observing the system employed in the operation of such a local Diagnostic Center, we find it housed in five pavilions, four of which are each divided by a central corridor into two wards. A ward contains twenty beds. The fifth pavilion has five spacious rooms, two of which are for patients, three being reserved for the x-ray department.

The distribution of patients in the different pavilions is as follows: The first is used for the reception of new cases; the second is used for purposes of observation; the third receives the "closed," and the fourth the "open" tuberculous forms. The

left ward of the fourth pavilion is reserved for those patients whose condition is such that they are not susceptible of transportation. These are cases in which tuberculous localizations have been ascertained bacteriologically.

The patient entering the Center with the diagnosis of pulmonary tuberculosis is escorted to the reception room in the first pavilion, where he discards all his clothes. Thence he is admitted into the ward, unless the clinical record shows that his sputum has been found positive for the Koch bacillus. If that is the case, he is sent directly to the left ward of the fourth pavilion, as noted above.

The day following the patient's entrance the examination of the sputum is made in the laboratory attached to the Center. If the examination is positive the patient is transferred to the fifth pavilion. If negative, he is placed in the second pavilion, where he remains until the investigation of all data and the clinical as well as the radiological examination have permitted a diagnosis.

The examination of the patient consumes, on an average, six days. However, it must be understood that the actual examination does not require all of that time, for those who are discharged by reason of the disease, or allowed furloughs, must remain until all necessary measures coincident with military administration have been observed. In certain instances the men are detained for a longer period in order to renew all clinical, bacteriological, and radiological researches.

In any case, when the diagnosis of tuberculosis is not reached, if the patient is not found to be affected by any disease whatsoever, he is ordered to return to his regiment. This may occur directly, or after a leave of absence. However, if he is found to be in an impoverished physical state, or in a condition of marked oligemia (although not declared affected by tuberculosis), or if he is in any way affected by a condition that renders him temporarily unfit for military service in the first line, he receives some other assignment while arrangements are made to grant him a leave of absence. This leave is rarely longer than three months.

Those who are not affected by pulmonary tuberculosis, but who show signs of other diseases, such as organic heart affection, general and serious constitutional impairment, etc., are sent to the General Central Hospital, which takes care of such cases.

Those who are affected by pulmonary tuberculosis are subject to procedures which differ according to the findings of the sputum examination. The pulmonary cases which are found to be closed forms of the disease are sent to the Central Hospital, from which, if necessary, they are transferred to the Sanatoria. If a pulmonary case develops an open form the man is immediately sent home, definitely discharged from the army. In that case a medical report is prepared and all clinical, bacteriological, laryngological, and radiological records are incorporated therein, together with a chart of the patient's temperature, and the whole forwarded forthwith to the Central Sanitary Board at the War Office. There the papers are viséd and returned to the hospital whence they originated, where the discharge is made effective. If the case is that of an officer, the declaration of the disease must be made

by a special Board of Medical Officers, thereafter to be viséd by the surgeon in charge of the hospital and by the surgeon in charge of the Medical Department of the Army Corps of the relative war zone.

This procedure takes four or five days for a private and about two weeks for an officer.

Before the patient returns home he must first pass through the quarantine department of the Army Corps, which is established for the prevention of infection of the war zone with the various contagious diseases existent in civil communities, and vice versa. The civilian health board of the community wherein the patient resides is informed of his discharge, so that it may exercise proper care and supervision.

Plans are now being made for further treatment of those patients who have been discharged from the army, instead of returning them to the more or less unrestricted freedom of civil life. These plans, when developed and placed in operation, will not only protect society, but will serve for educational purposes, since it has been found that civilian authorities (local health boards) do not always provide the proper protection.

One of these local Diagnostic Centers received 1,327 patients during the first seven months of 1917, with an average of 7.3 patients per day. There was a progressive diminution of the figures of the closed forms which shows an equally progressive improvement of the technique of selection. The following table gives the movement in detail.

TABLE SHOWING THE RETURNS FROM THE DIAGNOSTIC CENTER OF THE THIRD ARMY CORPS FROM FEBRUARY TO JULY, 1917

RECOGNIZED AS AFFECTED BY PULMONARY TUBERCULOSIS.														
Month.	Suspect Cases Admitted.		With Positive Sputum.		With Negative Sputum.		Totals.		Recognized as Healthy and Returned to Organization.		Discharged but not Tuberculous.		Totals.	
			No.	Per Cent.	No.	Per Cent.	No.	Per Cent.	No.	Per Cent.	No.	Per Cent.	No.	Per Cent.
February.	166	36	21.6	67	40.4	103	62	27	16.3	36	21.7	63	38	
March....	212	45	21.2	44	20.7	89	41.9	47	22.2	76	35.9	123	58.1	
April.....	225	46	20.5	34	15.1	80	35.6	57	25.3	88	39.1	145	64.4

June.....	207	45	21.7	19	9.2	64	30.9	11	5.4	132	63.7	143	69.1	
July.....	291	66	22.6	22	7.6	88	30.2	6	2.1	197	67.7	203	69.8	
Total....	1327	280	21.1	204	15.3	484	36.4	167	12.7	676	50.9	843	63.6	

From the clinical point of view it is interesting to examine the data given above. Rare indeed are the third-stage cases (*i. e.* seriously diffused and cavity forms) which reach 9.9 per cent., while the initial infiltration of the apices reach 68.7 per cent. Equally rare have been the florid rapid cases, showing only 2.6 per cent.; and the number of dormant-form cases, whether light or serious, is small indeed.

The anamnesis of each patient has proved to be of great importance, for with its aid the disease can be traced from its very beginning, hereditary faults frequently being revealed by their appearance. We must include, also, the evidences of a weak constitution, lack of resistance to the demands of military life, past history of frequent spells of

coughing which, much to the shame of the medical profession, are improperly called "colds." And we may add to the foregoing the lymphatic and scrofulous manifestations of infancy, the past pleurisy—all of which doubtless form valuable elements of presumption. Some patients date the appearance of the disease from an attack of the grippe; some to a definite attack of hemorrhage that appeared after or during exertion or some particular fatigue. In other cases it was attributed to an attack of pleurisy, or any acute disease, such as typhoid fever, etc. In still others it was traced to a trauma, a wound, to wounds of the lungs by bullets, blows on the chest, sudden displacement of the air due to explosions, or to the inhalation of poisonous gases, and in one case to antityphoid vaccination.

Thus, from the gathering of different data the modern idea as to the epidemiology of tuberculosis and its pathology has been again vindicated; that is, that the disease in the adult must be generally considered as the *awakening* of an old process or lesion, or of a latent infection. It would seem that the application of these findings to tuberculosis in the army develops a very important fact, and that is that military life itself does not initiate the disease, but it does provide conditions which diminish the resistance of the body so that it is not difficult for an old process or a latent focus to awaken to activity.

Consequently, and in all justice, all cases of tuberculosis that are discovered among the enlisted men should be considered as having been caused by the war. This conclusion seems to be the most natural one, for it is undeniable that without the hardships, the active operations in the field, the trauma, or the irritating action of poisonous gases, etc., the majority of those cases would have remained latent or inactive. So long as the men were living under civilian conditions they were apparently healthy, not only supporting themselves but their dependents. It required the rigors of military life and the hardships of the battlefield to awaken the disease and render them invalided, possibly for the rest of their lives.

And by means of this wise plan of the Italian government there has been provided a way to deal generously with those unfortunate men who have come under the shadow of the disease—who were not even so fortunate as to fall on the field of battle.

ACUTE LARYNGITIS WITH EDEMA OF THE GLOTTIS;

REPORT OF THREE CASES REQUIRING INTUBATION; RECOVERY.

By LOUIS FISCHER, M.D.,
NEW YORK.

DURING the past winter I have been impressed with the large number of cases of laryngeal stenosis requiring intubation. In almost all of these cases there was an acute catarrhal rhinitis, with marked lassitude, cough, anorexia, and fever. The temperature averaged 102° on the first day of illness, and rarely reached higher than 103° on the second or third day. The pulse rate showed greater variation, as it ranged between 140 and 160. In some of the very toxic cases the pulse rate dropped from

100 to 90, 80, or even 70 after three days of illness. In all of the cases the pulse was irregular and intermitting.

Cultures taken from the throat showed the absence of the Klebs-Loeffler bacillus, but smears showed, in addition to the *Micrococcus catarrhalis* and the pneumococcus, the *Staphylococcus pyogenes aureus*. As more than one member of a family was affected, it was believed to be a communicable affection; hence isolation was ordered whenever possible.

CASE I.—M. R., eighteen months old, was seen by me, in consultation with Dr. S. Herrmann, on the ninth day of illness, with the following history: Present illness began with cough, rhinitis, and fever; later spasmodic cough, croup, and hoarseness. Fifteen thousand units of diphtheria antitoxin was injected within twenty-four hours. Stenosis was so severe that intubation was performed. Extubation was followed in one-half hour by severe stenosis requiring reintubation. The tube remained in the larynx two days, when a severe coughing paroxysm associated with cyanosis followed. The tube could not be palpated in the larynx and was probably swallowed. A new tube was then inserted, this being the third intubation. The temperature rose to 105° and gradually came down to 100.8°.

When first seen by me the pulse was 120, respiration 36. Owing to the strict supervision demanded by intubated cases I sent the child to the Minturn Hospital September 21, the ninth day of illness. I extubated the two-year size tube and inserted a three-year size. This was the fourth intubation. During the following week there was thorough oxygenation, no stenosis, no retraction, heart sounds clear, color good, and no cyanosis. On September 27 the patient was extubated. Forty minutes later it was necessary to reintubate. Six hours later the tube was swallowed. I then introduced a size two tube dipped in hot gelatine containing 10 per cent. ichthyol. This medicated tube was left in the larynx five days when the patient swallowed it. Reintubation was unnecessary as there was marked retraction for a few moments only. Patient was discharged cured a few days later.

CASE II.—Milton F., seven years old, was seen by me in December, 1917, in consultation with Drs. Ritter, Clinton, and Feinberg, on the second day of illness. He had received 5,000 units of diphtheria antitoxin. There was cyanosis, with marked retraction in the subclavicular region and laryngeal stridor.

From the previous history I learned that the child had had an attack of diphtheria four years ago and received antitoxin. Later had an attack of nephritis. Has been subject to recurring tonsillitis every winter. Has had chickenpox, and measles twice.

The pulse was irregular and intermitting, the skin was livid in color due to deficient oxygenation. Wheezing with coarse mucous râles was heard on both sides of the chest posteriorly. There was slight dullness on percussion at the base of both lungs, and with acute pulmonary congestion the beginning of pneumonia was suspected.

Several attempts at intubation had previously been made and it was with considerable difficulty that I introduced a five-year tube. The epiglottis was thickened and almost rigid. No force was used, but the tube was slowly guided into the chink of the glottis. The cyanosis disappeared after a large quantity of tenacious secretion was coughed up.

The child was sent to the Minturn Hospital for better supervision and nursing. Five thousand units of diphtheria antitoxin was ordered on admission. Steam vapor was used to relieve coughing paroxysms, and a hypodermic injection of codeine, $\frac{1}{4}$ grain, was given at 8.45 P.M., and repeated in two hours. The condition improved. The appetite improved until the fifth day when a severe urticaria covered the entire body. This serum rash caused considerable itching, which was relieved by bicarbonate of soda paste applied over the body, also a 5-minim hypodermic injection of adrenalin chloride, 1 to 1,000. The tube was removed on the seventh day with no recurring stenosis. Hoarseness and cough continued for a number of days. This was relieved by steam and small doses of glycerin.

CASE III.—M. M., two years old, was seen by me, in consultation with Dr. J. Littenberg, with the following history: Breast-fed infant, walking at eighteen months. Had a convulsion six months ago. The temperature when first seen was 105°, pulse 150, respiration 36. Had a convulsion in the morning lasting one hour. There was labored breathing, with marked retraction of the chest and laryngeal stenosis. Five thousand units of diphtheria antitoxin had been injected. It was decided to intubate. A two-year tube was inserted. Immediately following the intubation the child had a severe convulsion. The hands and feet were cyanotic. I removed the two-year tube and inserted a one-year tube. This seemed to relieve the labored breathing, the color returned, and the child became more comfortable. The child was seen again four hours later when it was found that the breathing was quiet; there was no retraction of the chest.

A consolidation of the lung was located and extubation was performed. Laryngeal stenosis did not recur. The pneumonia progressed favorably and the child made an uneventful recovery.

It is interesting to note that the tube remained in the larynx but a few hours, which gave sufficient time to cough up catarrhal secretions, and sufficient mechanical dilatation was evidently accomplished by the tube remaining *in situ* for four hours. The culture was negative as to the Klebs-Loeffler bacillus.

From a study of the three cases here described, we find all presented the same class of symptoms—rhinitis and catarrhal manifestations of the nasopharyngeal tract several days prior to the acute laryngeal stenosis. There was fever in all cases. The temperature ranged between 102° and 105°; it invariably rose two degrees after antitoxin was administered. The pulse rate was accelerated and rose from 110 to 140 in several cases. The respirations were labored and the frequency was double that of the normal child. These catarrhal symptoms were associated with a barking, rasping, or croupy cough, and in several cases with marked respiratory interference. The cyanosis of the lips and face was also manifest in the hands and fingers—a distinct circulatory disturbance. There were also marked retraction of the chest walls, overacting intercostal muscles, and accelerated and difficult breathing. The retraction at the ensiform cartilage and at the epigastrium was distressing at each inspiration.

Deductions from the symptoms just mentioned would indicate that a stenosis of the larynx was present. On palpation the epiglottis was found swollen, the larynx was thickened, hardened, and infiltrated, and it was with considerable difficulty that an intubation tube adapted for the age was introduced. Such tube usually remained in the larynx two or three weeks, and was then coughed up. In one case the tube remained but four hours. In another case the child coughed up and swallowed tubes twice in one week.

Several points should be remembered in the management of laryngeal edema. Be careful not to force a tube into the larynx even though the size may be suited to the child's age. In one case an attempt was made to introduce a three-year tube in a child of three years, the tube could not be inserted, and apnea followed, which immediately improved on withdrawal of the distal portion of the tube. A two-year tube was also introduced with difficulty, so a one-year tube was tried. This proved to be the proper sized tube for that particular case. The clinical picture changed within six hours, the edema subsided, and as the small tube was coughed up a two-year tube was used. This tube remained *in*

situ for two days, and was then coughed up. Twenty minutes later a three-year tube was inserted. This tube remained six days. On extubation stenosis recurred after twenty minutes. A two-year tube covered with a gelatin film containing 5 per cent. of ichthyol was then inserted. The child wore this tube for several days, finally coughed up the tube, and has remained well.

All cases should be given sufficient antitoxin. Do not expect a laryngeal stenosis to improve by giving less than 5,000 to 10,000 units of antitoxin. It is preposterous to expect specific results in membranous or even nonmembranous laryngitis when thickening due to edema causes stenosis. There is marked danger from the acute swelling unless the same is modified by intubation. But time should not be lost. When, however, intubation has accomplished its result in relieving stenosis, as in the third case reported by me, then the tube should be removed, otherwise it acts as a foreign body.

A laryngeal spray of 1-2000 adrenalin chloride, or a local application of adrenalin by means of a swab, several times a day, has a very soothing effect. One-grain doses of sodium iodide will relieve and reduce the swelling in the larynx. If the child is very anemic, 5 to 10 drop doses of syrup of iodide of iron, three times a day after meals, is a good restorative and should be tried.

The after-treatment consisted in giving one-grain doses of thyroid extract, three times a day for one week. This thyroid extract was given to stimulate the internal secretions and to supply the supposed deficiency of thyroid. This was followed by Basham's mixture, one drachm three times a day after meals. To stimulate the circulation tepid tub baths followed by cold spray or shower and massage were ordered daily. The bath and shower were given to stimulate the circulation and as a vasomotor tonic. Excellent results followed this plan of treatment both as to the circulation and as a general restorative.

Résumé of Diet for a Child of Two Years or Older.—During the febrile stage skimmed milk and sour (Bulgarian) milk were ordered. For thirst orange juice and pineapple juice were given. After the febrile period subsided farina, oatmeal, cream of wheat, steamed rice, junket, spinach, raw scraped apple, apple sauce, grapes, ice cream, toast, zwiebach, and jelly were given. Later chicken and lamb were added to the dietary.

155 WEST EIGHTY-FIFTH STREET.

DIFFERENTIAL DIAGNOSIS AND TREATMENT OF FOLLICULAR CONJUNCTIVITIS.*

By WILLIAM MERLE D'AUBIGNE CARHART, M.D.

NEW YORK.

OCULIST, BUREAU CHILD HYGIENE.

LAST year I had the honor to read before you a paper on the Diagnosis and Treatment of Trachoma.† Since follicular conjunctivitis is rather intimately associated with trachoma in the work we are

*Read before the Oculist Conference, Bureau of Child Hygiene of the Department of Health, December 15, 1917.

†MEDICAL RECORD, January 6, 1917; also Reprint Series No. 59, Bureau of Public Health Education, Department of Health.

doing at the Children's Clinics of the Bureau of Child Hygiene, it has seemed advisable to follow up my former paper with a similar one on follicular conjunctivitis. A very large proportion of the children sent to the Children's Clinics by the medical school inspectors and school nurses for chronic sore eyes do not have trachoma, but do have follicular conjunctivitis. In the early years of the eye service of the Department of Health when the trachoma crusade was being put into effect under the leadership of Dr. H. W. Wootton there was naturally some confusion in the differential diagnosis between trachoma and follicular conjunctivitis, and many cases which we would now call follicular conjunctivitis were included under a hasty diagnosis of trachoma. Much good and no harm was accomplished by the trachoma crusade despite this confusion in differential diagnosis, since our vigorous medical and surgical methods resulted in the cure of these cases of follicular conjunctivitis as well as of cases of genuine trachoma. As even now there seems to be some lack of clearness in the differential diagnosis of these two diseases, as shown by our varying diagnostic data on case histories, I am venturing to present to you my own ideas of this differential diagnosis in the hope that a discussion of my paper by my associates in the eye service may prove useful in systematizing our clinical records and in increasing the efficiency of our work in the Children's Clinics.

The clinical picture of a case of severe trachoma is perhaps distinctive enough to avoid any error in diagnosis, but it is the border line cases and the cases of moderate degree of severity complicated by mixed infection which have led in the past to differences of opinion as to what is or is not trachoma. Unfortunately these border line cases and these mixed infection cases are in the great majority so far as frequency of occurrence here in New York City is concerned, and therefore for us who are treating the children for eye disease in the Children's Clinics this question of differential diagnosis between trachoma and follicular conjunctivitis becomes most important for the success of our work in child hygiene.

In order to be clear and concise in giving the differential diagnosis between follicular conjunctivitis and trachoma, I shall be forced to appear dogmatic and perhaps unduly positive in my statements, but I shall be grateful for any differences of opinion you may express. In the first place follicular conjunctivitis is essentially an exceedingly chronic condition, and in the absence of a mixed infection presents no secretion at any time of mucus, nor any evidence of inflammatory reaction of any sort. Trachoma on the other hand, while also here in New York usually a chronic disease, does show inflammatory exacerbations at intervals and may have considerable secretion of mucus during these exacerbations. Follicular conjunctivitis never gives pannus nor involves the cornea even where the follicles are large and abundant. Trachoma, if untreated or badly treated, will sooner or later give some corneal involvement, possibly not pannus but surely a corneal haze or circumcorneal ciliary injection. Trachoma can be divided in its progressive course into three stages, ending unless cured by treatment in complete cicatrization of the

palpebral conjunctiva. This cicatrization of the conjunctiva is nature's method of cure, but before its completion vision is apt to be irretrievably damaged by corneal complications. Our aim in treatment should be therefore to get rid of the disease before corneal complications have opportunity to develop. Follicular conjunctivitis presents no distinctive stages, nor does it ever give any cicatrization of the conjunctiva. Apparently it begins in the same form in which it continues and merely extends and enlarges its follicles as first seen. Follicular conjunctivitis is largely a disease of the superficial layers of the conjunctiva and is localized therein, while trachoma always involves the deeper layers down to the tarsal cartilage. On inspection of a case of follicular conjunctivitis, for this reason, we see no marked change in the capillaries either in size or number, and the tissue between the follicles on the surface of the conjunctiva appears nearly normal both in color and lustre. In trachoma on the other hand the characteristic thickening and swelling of the whole lid structure causes the capillaries to be enlarged and the conjunctival surface to be everywhere altered both in appearance and color, while the trachoma granulations tend to coalesce into masses surrounded by a general infiltration and vascularization of the entire conjunctival tissue. In follicular conjunctivitis, as we usually first see it in New York City schools, the follicles often begin as small pinkish eminences sparsely arranged in parallel rows on the surface of the lower lid, and only later do they develop by increase in size and number to cover a good portion of the lid surface even encroaching en masse upon the fornix as sago-grain vesicles. Trachoma granules seem to involve both lids early in the disease and are particularly abundant in the upper fornix. A very early sign of trachoma, which I have never seen stated in any textbook or article, but which I have noticed time and again, is an involvement of the ocular conjunctiva in the form of a ring of gelatinous granules deep in the fornix and gradually spreading forward to a considerable distance on the eyeball. This sign can be seen early in trachoma by causing the patient to look down very strongly and then gently raising, not everting the upper lid. It never occurs in follicular conjunctivitis, and seen in very early trachoma, when the inflammatory reaction is just beginning, is often overlooked. I think it always occurs in acute trachoma, or in trachoma with a mixed infection causing an inflammatory exacerbation of vesicular infiltration. It is not the uniform ocular vascularization we see in acute catarrhal conjunctivitis, and I believe is of some value as a pathognomonic symptom of trachoma.

In our work in the Children's Clinic it is *not* the well developed cases of either trachoma or follicular conjunctivitis which form the larger part of our eye service. Due to our efficient medical school inspection cases of follicular conjunctivitis and trachoma are sent to us early in their diseased condition, and we as oculists are called upon to make this differential diagnosis often before there are typical symptoms of either disease. As these incipient and border line cases must have a correct diagnosis made in order to give proper treatment, it is up to us to do our best to avoid error. Where

we see a child come to us with the upper lid surface entirely normal and the fornices not involved, but with a few rows of follicles on the lower lid, with no secretion of any kind, and the lower lid itself not vesicular that child does not have trachoma, but does have slight follicular conjunctivitis or folliculosis at any rate. But it is where there are granular masses irregularly distributed, even if confined to the lower lid, that uncertainty develops as to whether we do or do not have an incipient trachoma. I personally depend largely upon a study of the differential points I have just previously cited, and particularly to find out whether the diseased condition is superficial or deep. If I think there is even a beginning of swelling and thickening of the lid structure, I consider it trachoma as a provisional diagnosis. It does no harm to be cautious and to treat these cases as if they might be trachoma. I do not mean by that to treat these incipient cases with any radical means, but to keep them under close observation to see if the characteristic trachoma lesion does not develop either in the fornix or on the upper lid near the commissural fissures. Most of these cases do later on turn out to be trachoma.

As to treatment, I believe follicular conjunctivitis should be treated carefully in our Children's Clinics not because it is in itself a dangerous disease, but because it keeps the eye in an abnormal state where more serious infection is practically invited. For instance, the normal, healthy eye is usually resistant to chronic trachoma infection, as I have stated elsewhere, but given an eye affected with follicular conjunctivitis a trachoma infection is quite likely to follow on contact with another child who has trachoma. This explains, I believe, some of those cases which apparently begin as a follicular conjunctivitis and then develop suspicious symptoms leading us to doubt our first diagnosis. In these cases I convinced we have trachoma succeeding an original follicular condition. Mixed infections do occur.

Both follicular conjunctivitis and trachoma are apparently much less prevalent than in 1902 when the trachoma crusade began in New York City. As sanitary conditions have improved immensely of recent years, and as medical inspection is now more rigid and efficient, it may very well be that a considerable part of this diminution of infectious eye diseases is due to the general sanitary improvement as well as to the effectiveness of our treatment of these diseases in the Children's Clinics.

We do not now urge expression for those cases we know to be follicular conjunctivitis, although if it were justifiable, which it is not, many severe cases of follicular conjunctivitis with large abundant follicles could be easily cured by expression. As to medical means, like most chronic diseases, each oculist has his favorite application for follicular conjunctivitis; so it is with much diffidence I suggest citrate of copper ointment, 5 per cent, thoroughly applied to the follicles of the conjunctival surface. Massage, either in the form of the bichloride rub or of ophthalmol solution on a cotton wrapped applicator, will often cause the speedy absorption of the follicles of this disease. The main thought I leave with you in closing is that persistent and thorough massage treatment will accomplish far more cures

of follicular conjunctivitis than any special drug intermittently applied.

There are two suggestions I wish to offer to our staff officers on this subject of the treatment of follicular conjunctivitis and trachoma. First, it has occurred to me that a table of the differential diagnosis between follicular conjunctivitis and trachoma might be useful for the guidance of medical school inspectors and field nurses. In view of the possible extension of the work of the Children's Clinics in disease of the eye to other schools it seems to me important that the medical inspectors detailed in default of a sufficient supply of experienced oculists be trained to avoid mistaken diagnosis by the use of some such diagnostic table as I have the honor to present for your consideration.

<i>Follicular Conjunctivitis</i>	<i>Trachoma.</i>
Begins as small reddish elevations, sparsely arranged in rows on the conjunctival surface of the lower lid, extends later to the fornices, where large sago-grain follicles may extrude on everting the lids. Conjunctival surface between the follicles approximately normal.	Begins as irregularly placed granulations on both lids and fornices. Each fornix involved early in the disease. A ring of ocular congestion covered with glistening granulations extends outwards from each fornix over the eyeball. Conjunctival tissue is involved over entire surface of each lid early in the course of trachoma.
Blood vessels apt to be clear and distinct to view.	Blood vessels obscured by congestive infiltration of entire palpebral surface.
Lesion more superficial than that of trachoma, the follicles projecting from the conjunctival surface and not involving the entire lid structure.	Lesion deep, involving tissue beneath the conjunctiva. If untreated or badly treated, is sure to involve the cornea sooner or later. Terminates in extensive formation of scar tissue, whose roughened surface damages the transparency of the cornea.
Pannus never occurs.	Pannus apt to occur in long-standing cases.
Never involves the cornea in uncomplicated stage.	Mucopurulent secretion in acute stage and during any exacerbation.
No secretion of muco-pus. Very slightly communicable. Need not be excluded from school at any time.	A contagious disease.
	To be excluded from school.

Secondly, I respectfully suggest that an effort be made, perhaps through the publications of the Bureau of Public Health Education, to keep the medical profession of New York City informed of the work of the Children's Clinics, which is in my estimation one of the most practical and efficient branches of our public health service. In this way it appears to me misunderstanding might be avoided and the cordial support of the medical profession secured, an object which it is highly desirable we should obtain if our work for the children in the public schools is to be as successful in the future as in the past. In this day of the child the Cinderella of the Department of Health should emerge from her retirement and gain her merited recognition in preventive medicine and public hygiene.

616 MADISON AVENUE.

Rasmussen's Aneurysms.—Letulle refers to profuse hemoptyses from lung cavities in phthisis which are due to aneurysmal dilatations of a branch of the pulmonary artery in the cavity wall. This ectasia comes about secondarily to vascular changes induced by the presence of the cavity; concerning the mechanism of the process several causal factors may coexist. However produced the aneurysmal sac tends to rupture from progressive thinning of its wall as a result of secondary degeneration.—*Archives Médicales Belges.*

THE USE OF HORMONE EQUATIONS IN ACUTE INFECTIOUS DISEASES.

BY C. R. CARPENTER, M.D.,

EAST SAN DIEGO, CAL.

ORGANOTHERAPY has made great strides in the last twenty years, but the bulk of experience has been in its application to the treatment of functional and chronic diseases. Latterly much attention has been given to the study and treatment of organic disease of the ductless glands, and so absorbing has become this interesting and important study that the possible use of hormone therapy in acute infectious diseases has been almost overlooked.

Aside from malarial infections, trypanosomiasis, and more recently poliomyelitis, I know of no acute infections that have been successfully treated by this method. The experience of Roux and Lacomme in the treatment of trypanosomiasis has not been duplicated, and the treatment of poliomyelitis with adrenalin, while undoubtedly beneficial, was not in any sense specific.

The attitude of the profession towards the subject, that is, hormone treatment in general, is curious, to say the least, and shows how little we appreciate the tremendous importance of the work that is being done along this line.

Is it not a strange phase of medical science that while we have for centuries recognized that the body contained within it forces that endow it with a distinct resistance to the attacks of disease; that while we have for an equal length of time known that these same or similar forces also endowed the body with a power to recover from disease, we have never made any definite, organized attempt to locate these forces, isolate them, and use them in an intelligent, voluntary manner?

One of the commonest facts of life is that some people are healthy and some people are not. Some people are always "taking" this or that disease. Others do not readily take any disease. It is a common observation that several children in the same family may be exposed to the same disease, say measles or scarlet fever, part of them may take it and the others escape.

Formerly we used to explain this by saying, "Yes, Jimmie has a good constitution. He doesn't take the disease. He is all right, but Willie and Mary haven't so good a constitution." This with a grave shake of the head. In these days we use the word resistance in much the same cryptic manner. The term "good constitution" is now unconstitutional and is not used so much. Times have changed and with the changing have given us a new viewpoint of the same old thing with a different name.

The same is true of our attitude toward the treatment of disease. For centuries we have been deferring to that mysterious aggregation of forces which we know as the natural recuperative power of the body. The greater the advance in medicine, the greater has been our reliance upon it.

It is not long since it was a common thing in the treatment of severe cases for the consulting physicians to say, "Well, doctor, this is a serious case. We will just have to adopt an expectant treatment, etc., etc." Then they would all look as wise as they conscientiously could, for that meant simply that they did not know what to do for the patient, but

they did know that if they would just keep their hands off old mother Nature would cure the patient, perhaps, maybe, if possible. In other words, the profession had become so clearly conscious of the inadequacy of the treatment at their command, and were imbued with so much confidence in the natural power of the body to recover from disease that they felt they were giving the patient his best chance for recovery if they took no chances on interfering with the normal action of the vital forces.

Now it is interesting to inquire just how far beyond this point of view we have gone to-day. The physician to-day examines the blood, the sputum, the secretions of the throat and nose, the urine, feces, and spinal fluid, until he finds the invading germ or germs. And then he says, perhaps, "Well, we have here a mixed infection. I think we will use a stayphylo-strepto-pneumococcus-influenza combination." And then he says for the benefit of the unlearned, "Of course the best authorities admit freely that vaccines do not directly affect the disease, but experience has shown that they do have the power of arousing the defensive mechanism of the body. And when so aroused we find that this defensive mechanism throws out into the circulation what are called antibodies, which in turn destroy the germs, and in many cases their toxins, as well as stimulate the leucocytes to do the same."

How far have we gone? We have gone so far that we have gotten a new viewpoint of the same age-old vital forces and given them a new name. They are now called the defensive mechanism, and we have developed a method of using this mechanism that in directness at least is comparable to feeding liver to the cat that killed the rat that ate the malt that lay in the house that Jack built.

The wonder of it all is that such brilliant results should have been produced at times by such a method, and we can easily understand why it has so frequently failed. But it demonstrates more clearly that anything else could the first great principle that this paper is intended to lay down: *that the one great source of immunity from disease is within the body and not outside of it.*

Were it otherwise, the human race would have been swept out of existence by its invisible enemies, ancient as the earth itself. And this would have been done before it had time to emerge from a state of barbarism. All the science that man has been able to bring to bear upon the subject has done no more than enable him to assist and blindly stimulate these great forces, hoping and praying that the effect might be good and not evil. Much as the devil worshipper in darkest Africa goes to his fetish and prays, "O, great and powerful spirit, make this man well!"

Is it not about time then that the medical profession began to ask itself seriously, "What is this defensive mechanism? And where is it, that I may take it in my hands, carry it where I please, and use it in an intelligent and voluntary manner to prevent disease during health, and restore health during disease?"

Until very recently it was the prevailing opinion among those who thought enough about it to have an opinion that the source of immunity and resistance to disease lay primarily in the leucocytes. Many possibly cling to this idea. It is not long

since so prominent an investigator as Sir Almroth Wright expressed doubt that this was the case. Such a position is entirely untenable. In the nature of things whatever powers the leucocytes have must be conferred upon them by the organs that produce them. And it is well known that the action of the blood in resisting and overcoming disease germs lies more in the plasma than the leucocytes. It is now generally admitted that the action of the plasma is due to the antibodies contained in it.

But if the presence of antibodies in the plasma determines its effectiveness in combating disease, it becomes a very important matter to determine what these antibodies are, and especially their origin. When we determine their origin, we have determined the source of the body's resistance to disease, its power to recuperate from disease, and hence the source of immunity.

It has been shown by many observers that antibodies are present in the plasma to a greater or lesser extent even in health. When a vaccine is injected under the skin, something is stimulated to throw out more antibodies; something is aroused by this physiological spur. What is it that has been so stimulated?

Now we know that the endocrine organs are constantly throwing out into the circulation their internal secretions in the shape of hormones, which powerfully influence the functions and condition of the body in health and disease. We know too that it is perfectly possible to vary the amount of hormones secreted in several ways. Physiologically these variations are taking place more or less all the time in response to the varying emotions of the individual, sometimes being increased by stimulation of the organs, and sometimes being decreased by depressing emotions.

Again we know that hundreds of competent observers in all parts of the world have shown that it is perfectly easy to increase the amount of hormones secreted at will simply by the administration of the endocrine organs in appropriate form.

If, therefore, a vaccine or antitoxin injected under the skin or into the circulation stimulates anything to throw out antibodies, what is there to be so stimulated except the endocrine organs? And if the endocrine organs are so stimulated, what can they throw out into the circulation except their own hormones?

The answer to these questions suggests the second proposition which it is desired here to formulate: *There is ground for the belief that the antibodies and the hormones are identical.*

Engineers in driving a tunnel through a mountain frequently begin at opposite ends and drive towards each other until they meet. And so we have had two bodies of scientists that have been driving a scientific tunnel through a mountain of mystery. Unconsciously they have been approaching each other. The two ends of the tunnel are right together. Shall we not join them and throw open the tunnel to the traffic of human beings, so that the mountain shall no longer be a mystery? If the antibodies and hormones are identical there is but one conclusion that can be drawn, and this is the third and most important proposition to be

stated: *The endocrine organs constitute the defensive mechanism of the body.*

But no man's opinion or theory in this day of practical things is worth the paper and ink it takes to write it down, unless it is based on the facts of actual experience. And so it is desired to present here, not a theory, but an experience, and that experience translated into facts. No facts will be given that may not be duplicated by any one who will take the trouble to do so.

If the endocrine organs constitute the defensive mechanism of the body, then it is clear that by the administration of those organs or their products we should be able to prevent disease by increasing the body resistance at will; and in cases where disease has already become established in the body we should by the same means be able to restore it to the normal.

The writer first became convinced of the feasibility of such a method in the year 1900 when using the spleen in the treatment of malarial infections. The results of this work were published in 1906 without knowing of the work of Nouveau, which was published in 1902. The next year Paucot published his record-breaking account of his use of the spleen in malarial splenomegaly. Quite as important, however, as the immediate results produced in malarial infections was the discovery of its therapeutic limitations. Spectacular as are its effects in this condition, it failed utterly to give comparable results in other specific fevers. It was at first thought that it was going to prove valuable in typhoid, but subsequent experience disproved this.

But perhaps one of the most important developments from this work was, that in the treatment of hundreds of cases it was found necessary to combine the spleen with the products of other organs to meet special conditions; first with pepsin, to overcome the effects of anemia, and second, with the sex gland to prevent mental effects. The combination with pepsin alone, however, will also prevent mental symptoms, but it is only where the hormonal output of the sex gland is lowered that this effect, that is, mental symptoms, need be feared.

These combinations to meet special conditions suggested the thought that perhaps combinations of the spleen with other organs might give better results in other infections. So a regular campaign of combinations was entered upon, in which not only was the spleen combined with other organs, but other organs were combined without the spleen.

The first thing that suggested itself in regard to such a course was, Would not a combination of extracts of all the endocrine organs meet all conditions and cure all infections? This has been tried by other observers and proved a failure. But individual infections have been found by the writer to yield to special combinations, just as each infection as a rule requires for its treatment its special autogenous vaccine.

But here we find ourselves face to face with a gigantic problem: that of constructing combinations of organs that will produce specific effects in all the many infections that flesh is heir to. The problem that confronted the translators of the Egyptian hieroglyphics was not more hopeless in appearance than this. But to all cryptograms there is a key, we are told, and the key to this mystery

is to be found in the spleen. Although many useful combinations have been made in which the spleen does not occur, all those that have produced the most beneficial effects contain the spleen. So it has come to be looked upon as the central and most important organ of the defensive system; and the most of the building of combinations, or hormone equations, has been done by grouping various organs around the spleen, or by varying the proportions of the same organs.

It is not claimed that hormone equations have been constructed for all infections. Only a very small number out of the many that have been tried have proved specific; but enough it is thought to prove the truth of the principles involved, and blaze the way for the profession, by which, if it will, it may come into its own, and make habitual scientific use of those great vital forces that have so long escaped its grasp.

The infections in which practically specific effects have been produced are pneumonia, acute pneumococcic laryngitis, erysipelas, some pus infections, puerperal sepsis, measles, scarlet fever, and dysentery, both amebic and bacillary.

Although they cannot be classified as acute infectious diseases, it is just as well to mention in this connection, carcinoma and sarcoma. Two cases of the former and one of the latter have quickly disappeared under treatment and have not returned. It is hoped at some future time to present a more detailed account of the treatment of cancer by this method. Epithelioma strangely enough has not yielded to the same hormone equation, but it is thought that a slight change in the proportions may fulfill the indications and produce a similarly happy result.

At present a sufficiently large number of cases has not been treated to demonstrate the degree to which prophylactic results may be expected from hormone equations, but it is confidently expected that only further experience is necessary to show that such results can be relied upon. In prosecuting our investigations along this line, however, we should remember what we have learned by the use of vaccines and serums; that, as in the case of typhoid fever for instance, it requires a slightly different preparation for prophylaxis from that which is effective in clinical treatment. In some conditions, however, as in diphtheria, the same preparation may be used for both prophylaxis and treatment. The same differences may be expected in the use of hormone equations.

Indeed, as the effects of the vaccines and serums may be looked upon as simply an indirect use of the hormones, we should expect that the parallel would not stop here, and it does not. There is also more or less of a reaction, both local and general, where the hormones are used hypodermically, but the reaction is not so violent. The patient in such cases is not made so ill. This is probably due to the fact that the protein content is not so foreign to the circulation.

And yet it seems likely that we must fall back on the argument that primarily it is the introduction of a foreign protein into the circulation that is responsible for the reaction, and hence for the stimulation that produces the increased secretion of hormones. Every infection involves the impair-

ment of a certain group of organs whose hormones are necessary to the maintenance of the hormone balance. Hence if we inject into the circulation, or under the skin, a solution carrying the particular combination of proteins furnished by that group of organs, we have a right to expect, in obedience to Hallion's law, the stimulation of the same group of organs in the patient. Stimulation of an organ or group of organs, from the standpoint of endocrinology, can have but one effect—an increase in the output of hormones peculiar to that group. Hence, the hormone balance is quickly restored; and no germs or toxins can long remain in the circulation when this is done. Constitutional symptoms must cease; and the patient is on the way to recovery.

On the other hand, the internal administration of hormone equations in many cases restores the hormone balance, we must suppose, since constitutional symptoms cease and the patient recovers, without any reaction whatever. The effect is slower and less marked, but none the less certain. We must, therefore, believe that stimulation of the organs of internal secretion may be produced by the mere presence in the circulation of the protein which is characteristic of the group of organs to be stimulated, and which has been converted by the process of digestion into a form which is not foreign to the circulation.

Hence in the hypodermic method it seems to be true that we have a combination of two elements of causation upon which the effect depends: First, as when used internally, there is the presence of the specific protein of the group to be stimulated; and, second, there is an added stimulation due to the fact that the protein is in a form foreign to the circulation.

It is also true that some hormone equations, while markedly specific when given subcutaneously or intramuscularly, do not give comparable effects when administered internally. The effects are either much diminished or even wanting. This we might expect from our well-known experience in the use of pituitary, but it is true of equations in which the products of that organ do not occur.

At this particular time, when large numbers of men are being brought together in army camps where they are susceptible to acute infectious diseases, it is important that the possibilities of this specific treatment be recognized and made use of. Many lives have already been sacrificed, which the writer believes might have been saved. Measles and consequent pneumonia are producing havoc among the men who would not mind dying for their country if they could die on the field of battle; but to die of disease which might have been prevented, before they have had a chance to fire a gun, is as inglorious to them as it is devoid of good to the country. Now scarlet fever is setting in and will no doubt add largely to the total of lives thus ingloriously lost.

It is to be hoped that some effort will be made to stay the inroads of these diseases upon the vital strength of the nation, over and above the stereotyped methods. The latter do little enough in times of peace, but in a world crisis like the present, they only reveal the weakness of the profession in the face of a real emergency.

CHRONIC URETHRAL DISCHARGE.*

BY P. S. PELOUZE, M.D.,

PHILADELPHIA.

ASSISTANT SURGEON TO GENITO-URINARY DEPT., UNIVERSITY OF PENNSYLVANIA HOSPITAL; LATE CYSTOSCOPIST TO GENITO-URINARY DEPT. OF JEFFERSON MEDICAL COLLEGE.

WHEN we consider that many thousands of individuals are afflicted with a chronic urethral discharge, for the cure of which many thousands of dollars are being expended yearly, to say nothing of the mental suffering entailed thereby, there can be no question as to the immense social and economic importance of the subject. That patients can, and often do, carry a urethral discharge for many years must either mean that such conditions are extremely resistant to treatment or that there is something wrong with the treatment. Therefore, to be honest with our patients and with ourselves, it is our duty to endeavor to find where the real difficulty lies. It is neither just, nor to the best interests of medicine, for us to refuse to admit our failures if by so doing we can advance our understanding of disease and its treatment.

demonstration purposes before an audience, and would only serve to bring out the same points. A study of these case histories, as charted, shows some rather surprising facts well worthy of thought. The first three columns are very interesting, the next two are very illuminating, and seem to offer a possible solution to a large part of the trouble.

Twelve cases had been, without any close study, discharged by physicians as positively cured, and one was told that he should forget the shreds, as they meant nothing. Of the thirty cases only four had ever had any studies other than inspection of the urine, made to determine the true cause of their chronic discharge. Of these four, two had had a prostatic palpation and two had had a study of their prostatic secretions, but none of them had had any change of treatment thereafter that would hint that the examining doctor had discovered trouble. As a matter of fact, these secretions were 100 per cent. pus.

The columns giving the demonstrable underlying pathology are not without interest. The last column, showing the effect of treatment of this underlying pathology upon the urethral discharge, gives ample support for some of the thoughts to be brought out later. Of the two patients in whom the discharge was uninfluenced, one had a resilient structure for which he refused operation, and as his stricture would close down from neglect the discharge would reappear; the other had a tuberculous posterior urethra and lung.

As stated, a study of a large number of cases would serve to bring out the same points, and might change slightly the number who had had some form of examination, but the general result would be about the same. Such being the case, it is obvious that there must be rather general misunderstanding as to the reasons for such discharges, as well as to the treatment appropriate for their cure.

There are apparently many factors entering into this rather deplorable state of affairs, and it will be of distinct value to briefly discuss them.

For so many years the presence of a chronic discharge has been all that seemed necessary for a diagnosis of chronic urethritis that there is apparently no distinction made between the two in the minds of a vast majority of physicians. In other words, the so-called chronic urethritis has grown to be considered almost invariably a disease, whereas it is, beyond a question, almost invariably a symptom of some deeper-lying pathology. It has been deemed only necessary to establish the presence of a discharge to prove the presence of the urethritis, and a "diagnosis" so easily made has been simplicity itself for the busy doctor. Rarely does he think it necessary to carry his study further, but proceeds to use for an indefinite period those things which are said to be good for chronic urethritis. In very slight extenuation of this attitude might be mentioned the fact that the majority of general practitioners have a decided feeling against manually examining these cases, born of an exaggerated fear of transferring a gonorrheal infection to other patients. Cleanliness and rubber gloves remove such a possibility.

A close study of this symptom in a very large number of patients will show that a chronic discharge due solely to some pathology intrinsic to the

*Black-faced figures signify years; light figures months.

± signifies that, though some form of physical or laboratory examination was carried out, no change was made in treatment to suggest that anything was learned by such study.

³Refers to disappearance of discharge and not to cure of the underlying pathology. Case 1 had a stricture which upon neglect would bring about a recurrence of his discharge.

In an effort to arrive at the answer as to the most potent factors in the lack of success of the present-day treatment of these patients I have taken from my case records thirty histories, and tabulated what seemed to me to be the most important points. The records were taken as they came, without any selection whatever except that they had had a urethral discharge for four months or more. There is no special reason for limiting the number to thirty except that a larger number is unwieldy for

*Read before the Philadelphia Genito-Urinary Society, Oct. 29, 1917.

urethra is very much the rarity instead of the rule. In fact, if we exclude stricture, urethral growths, tuberculosis, and a very occasional case of multiple folliculitis of the anterior urethra, which together account for possibly 5 per cent. of all such discharges, it will be found that approximately 95 per cent. are kept up by some condition extrinsic to the urethra. If this is the case, it is very easy to see why the usual treatment of injections, irrigations, instillations, and dilatations exert about as much permanent benefit as should be expected of them. It is really hard to see how such forms of treatment could have any decidedly beneficial effect upon an infection deep down in the prostatic follicles, the seminal vesicles, or in Cowper's glands. Considering that the vast majority of these patients are receiving the forms of treatment appropriate and curative to only about 5 per cent. of them, it would be immeasurably better from the patient's standpoint, though far from ideal, if this anomalous condition were reversed and every one was treated for probable extrinsic lesions. Surely, under such a reversal of prevailing customs failures would be less frequent.

In the absence of the above-mentioned intrinsic lesions, and the frequent pseudotherapeutic attacks to which it is subjected, I am very strongly of the opinion that the urethral mucosa, with its unusually rich blood supply, will very seldom, if ever, hold a chronic inflammation unless subjected to the constant influence of some extrinsic irritating factor.

As acute specific urethritis is the chief etiologic factor in chronic discharges, the question that naturally arises is: In just what particulars does the usual treatment of this acute stage of the disease fall short that it predisposes these patients to a condition of chronicity?

Primarily, the anxiety of the patient to get rid of an acute discharge has made the physician feel, perhaps, that his reputation in such diseases depends upon speed. With the laity this is unfortunately true, and when a discharge does not speedily clear up it is often very hard to hold the patient's confidence long enough to complete the cure. It has become so much a habit to inspect the urine before the patient, that he follows his apparent progress even more closely than does the physician. The sole aim seems to be clear urine, and when this is obtained both assume the cure to have been accomplished. If, on the other hand, the shreds persist, the patient is far too often coaxed into a condition of mental quietude by being told that "they are of no importance whatever, and will probably never disappear."

The term "clinically cured" is far too frequently interpreted as a real cure, and yet an overwhelming number of patients who have a discharge of long standing have been "clinically cured." This term should be dropped, or else generally understood to mean nothing but an entire disappearance of discharge at the meatus and a perfectly clear urine. I have on dozens of occasions seen a persistently clear urine in the presence of countless numbers of pus cells in the prostatic secretions. I have seen patients who, so far as could be told, were clinically and microscopically cured as to all obtainable secretions, and who, two months later, had hundreds of pus cells in their prostatic secretions.

The question naturally arises: "When does one know a gonorrheal patient is cured?" and the answer, that we seldom really know, contains much truth. Surely, a clear urine is no proof that there does not exist a condition that sooner or later spells "chronic urethral discharge."

From a number of observations I am convinced that if we placed just one-tenth as much importance upon a thorough examination of our gonorrheal patients two or four months after an apparent cure that we do upon serological watching of our syphilitic patients, we would meet with many very illuminating surprises.

It is conceded by all authorities upon gonorrhea that from 60 per cent. to 95 per cent. of all cases of acute specific urethritis have a posterior involvement. The gonorrheal inflammation in these patients spreads over the entire urethral mucosa, and it appears to be rather generally assumed that by some wise provision of Providence it almost invariably leaves untouched the hundreds of mucous nooks and crannies in that anatomical sponge, the prostate, whose only outlets enter the urethral lumen at such a point that they must, from sheer gravity, be more or less continuously bathed in gonorrheal pus for days at a time. And treatment is applied to the urethra, where the drainage is fairly good; and the prostate, where the drainage must, from the nature of things, be wretched, is forgotten. I personally question whether an acute posterior gonorrheal urethritis ever leaves the prostatic follicles untouched.

There is another matter in this connection that seems to have received little, if any, attention, and which is, I feel, a potent factor in the spread of gonorrheal conditions to the seminal vesicles and epididymi. Belfield, in describing his operation of vasostomy, states that when the bladder becomes overfilled a few drops of urine will often exude from the opening in the vas deferens. It has been shown by injections of collargol through the vas that before any of it reaches the urethra it distends the seminal vesicle. I have upon several occasions demonstrated on fresh specimens from the cadaver that the reverse is true; *i.e.* that solutions injected into the ejaculatory duct distend almost to the bursting point the seminal vesicle before they find their way into the vas deferens. From these points I think we can draw two valuable conclusions: (1) An overfilled bladder is an element of danger in acute posterior urethritis, whether it be from urine or our irrigating solutions, and this possibly explains those cases of epididymitis following irrigation. (2) In cases presenting a history of epididymitis one should never forget that an inflammatory condition is more than likely to be present in the seminal vesicle of the same side.

Infections of Cowper's glands are, fortunately, rare, probably owing to the length and size of their ducts and their entrance into the urethra at a point rarely subjected to any great back pressure. When such infection does occur it usually eventuates in abscess formation. These glands, however, occasionally are the seat of chronic inflammation, and are then a factor in the continuation of urethral discharge.

Whether or not the startlingly large number of cases of tuberculosis of the genitourinary tract,

or elsewhere, that we find being treated as chronic urethritis, bear a direct relation to a previous gonorrhea that we so often find in their histories is hard to answer. However, the fact remains that he who entirely forgets tuberculosis as a factor underlying such discharges courts some sad surprises.

That there can be, and occasionally is, a chronic follicular prostatitis associated with a chronic urethral discharge in patients who have never been the victims of gonorrhea, and have not tuberculosis, stands without question, and it should not be forgotten in the natural tendency to question the veracity of such patients. Its care is in no way different from that following gonococcal infection, for it is usually due to the same bacteria that are secondary invaders in the specific cases after the gonococcus has died out, as it apparently does in the vast majority of the cases.

If the foregoing statements be true, and there is, I feel, no great difficulty in proving them to be so, we are brought to the realization that our efforts here, as in all other branches of medicine, should be directed at removing the cause rather than treating the symptom. Here, as elsewhere, it becomes a diagnostic question, and fortunately the diagnosis presents little difficulty to one who will spend a very short time in fitting himself to make it.

Beyond question, existing conditions in regard to chronic urethritis are largely due to the survival of many ideas that present-day clinical and laboratory methods have proved fallacious, and there need be no apology offered for concluding this somewhat rambling paper with a few rather dogmatic statements aimed at the ideas at fault.

He who treats genitourinary diseases from symptoms and the two-glass test will record few cures and many failures in this class of cases, for there are few examples in medicine where so-called cardinal symptoms more often mislead.

The microscope and cysto-urethroscope are inseparable from good work, and will correct many a faulty diagnosis.

The finger in the rectum can detect great prostatic pathology, but nothing but the microscope can give the prostate a clear bill of health.

A palpable seminal vesicle is not always a diseased one, and a diseased one is not always palpable. The microscope can rule out pathology here if the secretion is obtainable, and probably nothing but operation if it is not.

Burning on urination that has no direct reference to treatment is seldom a symptom of chronic urethral discharge in the absence of tuberculosis; always suspect and study it.

A urethral discharge will almost invariably disappear early when the underlying cause is receiving proper attention. If it persists, suspect your diagnosis; it is probably wrong.

1831-33 CHESTNUT STREET.

Aerated Water in Severe Angina.—The use of siphons of seltzer in severe anginas, including diphtheria, was apparently first introduced long ago by Labrube. Comby has recently revived its use and speaks highly of it in all severe types of sore throat. It is chiefly indicated in very young children, but may be used with profit at any age.—*La Presse Médicale*.

AUTOSENSITIZED FOREIGN PROTEIN;

CLAIM OF SUPERIORITY FOR IT AS A SUBCUTANEOUS OR INTRAVENOUS INJECTION.

BY WILLIAM LEE SECOR, A.M., M.D., F.A.C.S.,

KERRVILLE-ON-THE-GUADALUPE, TEXAS.

THE use of subcutaneous or intravenous injections of a foreign protein is becoming a very popular therapeutic procedure in the management of various diseases.

In the medical literature of the past few years we may find many excellent articles dealing with every phase of foreign protein therapy as worked out in laboratory and clinic. Many of our laboratory men and some of our leading clinicians are of the opinion that the benefit derived from the use of mixed stock vaccines is simply the benefit that would be obtained from the use of any other properly prepared foreign protein.

The conditions which have probably received the most careful study in regard to the therapeutic effect of the subcutaneous or intravenous injection of foreign proteins are arthritis, pellagra, psoriasis, and pneumonia. Some are very enthusiastic and make rather extravagant claims, while others are probably too conservative. I think, however, that clinicians who have made careful trials of this therapeutic procedure in these conditions are pretty well agreed in the opinion that at least as an adjunct to other forms of treatment, it is of considerable value. My personal experience with foreign protein therapy has been more largely in connection with the treatment of pellagra than with that of the other diseases mentioned.

In the *Journal of the American Medical Association*, of May 8, 1915, I published, in collaboration with Dr. E. E. Palmer, a report of the treatment of seven cases of pellagra by the injection of the serum obtained from a blister produced on the body of the patient by the use of cantharides plaster. Since that report, we have ourselves treated and received reports of treatment of hundreds of cases of pellagra with the most gratifying results. The technique of the procedure as we carry it out was described in the *MEDICAL RECORD* of July 17, 1915.

Probably the most recent work published on foreign protein therapy is that of Dr. Frank J. Scully, Research Fellow at Cook County Hospital. Dr. Scully's work was done on psoriasis. He used typhoid vaccine as the foreign protein and administered it intravenously. He records favorable results and considers it a valuable adjunct to other forms of treatment. He refers to the use of auto-serum by Gottheil, Satenstein, Fox and Hilario and says: "The use of intravenous vaccines has the advantage of easy administration, but has the disadvantage of a more or less marked reaction following the injection, necessitating that the patient remain in bed for from eight to ten hours. The auto-serum injections, on the other hand, can be given in the office or the dispensary, but their preparation requires time and care, with a consequent danger of infection."

In our research work at the Kerrville Hospital we have used single vaccines, mixed vaccines, phylacogen and auto-serum. We find that the great objection to the use of phylacogen and vaccines is the

marked reaction obtained. Autoserum, however, produces very little or no apparent reaction.

Dr. J. B. Murphy, in an attempt to lessen the reaction and increase the therapeutic value of the autogenous vaccines that he used, employed what he called "autosensitized vaccines." He said: "In order to obtain the best results from vaccines, not only should the microorganisms come from the patient himself, but this autogenous strain should be cultivated upon the patient's own blood-serum, thus giving an automedium. We believe the autosensitized vaccine is a decided advance in the vaccine treatment of disease." He found that a much larger dose of autosensitized vaccine could be given without apparent reaction. He could not explain it, but simply noted it as a clinical fact.

I think that all of those who have made a clinical comparison of the action of injected foreign protein of the vaccine type with that of autoserum will agree, that in therapeutic effect the autoserum is fully equal, if not superior, to the vaccine, that very much less apparent reaction follows either the intravenous or subcutaneous use of autoserum than follows the same use of vaccine, and that the only real drawback to the use of autoserum is the difficulty of preparing and storing it as it is now generally prepared and handled.

The purpose of this paper is to acquaint those who are interested in this department of therapeutics with the fact that in my hands, during an experience of over four years with autoserum therapy, I have found that the blister serum, before noted, has all of the advantages and none of the disadvantages of serum obtained from defibrinated blood, to wit:

1. It is just as potent therapeutically as any other foreign protein. (Much more so in pellagra).
2. It produces little or no reaction.
3. It is easy to obtain—patients do not object.
4. After hundreds of injections, I know of not one harmful result,—not even a local abscess.
5. The technique of obtaining and using the serum is so simple that any physician can use it, no matter how isolated he may be.

This blister serum I am in the habit of thinking of, in the light of the teachings of Murphy, as an autosensitized foreign protein. Some hold that autoserum obtained from whole blood should not be regarded as a foreign protein. However that may be, there is no question but that the blister serum is foreign for the very process of the serum formation makes it so.

To obtain the blister serum we wash a small area of the chest with alcohol, place on it a piece of cantharides plaster smeared with oil, one and one-half inches square, and cover it with a perforated aluminum eye shield, such as is used after cataract operations, held in place by adhesive strips.

We place this plaster on in the evening, and by the next morning from one to three cubic centimeters of serum will usually be formed. There is quite a difference in different cases as to the time and amount of serum formed. In several cases forty-eight hours were required to produce one cubic centimeter of serum.

The shield is removed, an upper corner of the plaster is raised, and the serum withdrawn by a sterile hypodermic syringe. The desired amount is

then immediately injected into a vein or the subcutaneous tissues of the arm.

The plaster is then carefully removed and the skin area dressed with a sterile gauze pad smeared with sterile petrolatum. If done properly there is no pain and very slight discomfort. No patient under my observation has objected to repeated treatments.

While we have seen pellagrins get well during the administration of the autoserum treatment alone, without change of diet and after arsenic, quinine, etc., had failed to cure, yet we find that in this disease at least, much more rapid results are obtained if arsenic and a generous diet are administered during the treatment.

Medicolegal Notes.

Provision of Harrison Anti-Narcotic Act Held Unconstitutional.—Harrison Anti-Narcotic Act, Dec. 17, 1914, c. 1, 38 Stat. 785 (Comp. St. 1916 §§ 6287g-6287q) provides for registration of and the imposition of a special tax upon, all persons who produce, import, manufacture, compound, deal in, sell, distribute, or give away opium or coca leaves. Section 2 (section 6287h) provides that it shall be unlawful for any person to sell, barter, exchange, or give away such drugs except in pursuance of a written order of the person to whom such article is sold, on a form issued in blank for that purpose by the commissioner of internal revenue, and that every person who shall accept any such order shall preserve it for a period of two years in such a way as to be readily accessible to inspection by any officer, agent, or employee of the Treasury Department, but that nothing contained in the section shall apply to the dispensing or distribution of such drugs to a patient by a physician, dentist, or veterinary surgeon, provided that such physician, etc., shall keep a record of all drugs dispensed or distributed, showing the amounts dispensed or distributed, etc., or to the sale, dispensing, or distribution of any such drugs on a prescription issued by the physician, provided that such prescription shall be dated as of the date on which it is signed, and shall be signed by the physician, etc., and preserved by the dealer. An indictment in the words of the statute alleged that the defendant, a Texas physician, who had duly registered and paid the special tax of one dollar, did unlawfully and knowingly sell and give away a quantity of heroin tablets, which sale was not made in pursuance of a written order on a form issued in blank by the commissioner of internal revenue. A second count of the indictment was identical with the first, except that it charged that the defendant did unlawfully, knowingly, and willfully sell, dispense, and distribute heroin tablets not in the regular course of his professional practice, and not in the treatment of any disease, but to a person who was then addicted to the drug habit.

The federal district court for the Western District of Texas held that the two counts in the indictment did not state offenses against the laws of the United States. The acts charged to have been omitted and committed were violations of police regulations incidental to the taxing purpose of the act, and did not tend to render effectual its prime object, revenue. To that extent the act was held to be in violation of article 10 of the amendments to the Constitution of the United States, providing that the powers not delegated to the United States by the Constitution, nor prohibited by it to the states, are reserved to the states respectively, or to the people. Nine years before the passage of the Harrison Act the State of Texas, in the exercise of its reserved power of domestic regulation, passed certain laws, penal in character, which restricted and limited the sale and disposition of opium and its derivatives. The provisions of that regulatory act are in many particulars substantially the same as in the federal revenue bearing and taxation act.—United States vs. Doremus, 246 Fed. 958.

Military Medicine.

Minor Maladies in Flying Men.—Surgeon A. E. Panter, writing in the *Journal of the Royal Naval Medical Service* for January, 1918, says that during the past eighteen months his duties have led him into the hitherto somewhat unstudied, or perhaps more correctly unpublished, sphere of sickness associated with flying. While many inexplicable symptoms attributed to lack of oxygen and other abstruse causes do undoubtedly occur, he has time and again been much impressed by the simple explanation of various ailments complained of by pilots as "coming on" whilst in the air, and frequently on questioning has obtained a history of "feeling out of sorts" before going up. Although there is nowadays an explanation for most of the fatal accidents occurring in the air services, there is always a percentage in which the cause remains a mystery. He is convinced that in a large proportion of these mysterious crashes the cause is loss of consciousness by the pilot. He has had at least four cases of pilots completely losing consciousness in the air. Two of these "crashed" on trying to land, which apparently they did subconsciously, without severe injury to themselves, the other two both lost consciousness at a height, subsequently regaining it, and were able to recover control of the machine and make safe landings, both feeling extremely ill. He has often noticed how greatly any alimentary disturbance becomes exaggerated in the air, and several cases of vomiting while flying have occurred apart from vestibular vomiting experienced by some pilots on extremely "bumpy" days. In these cases also the pilot, on questioning, has admitted having had slight indigestion before going up. A common cold when accompanied by much nasal catarrh will often give rise to great trouble at a height, and especially during rapid diving, and several times pilots with this condition have come for advice wishing to ascribe their symptoms to a "lack of oxygen," but with the curing of the cold the trouble ceases. In one case epistaxis accompanied the difficulty in breathing in a pilot flying with severe nasal catarrh. This pilot had never experienced any signs of distress, though he had done regular patrols of one or two hours' duration at 17,000 to 18,000 feet during the past three months.

It is extraordinary, considering the number of high patrols, 17,000 to 20,00 feet, carried out daily by the wing to which Surgeon Panter was attached how rare it was to find any pilot with symptoms attributable to lack of oxygen. The writer is convinced that there must be certain factors which tend to compensate for the decrease in atmospheric pressure. Intrapulmonary pressure is probably augmented, with increased ventilation of the air cells, so that what is lost in quality of inspired air is to a certain extent made good in quantity. For efficiency in the air, robust health is essential. Any minor disability becomes greatly accentuated when the general nervous system is at high tension, as during flight, and there is not the slightest doubt that many "crashes" and "nervous breakdowns" could be averted if all minor maladies were taken in time and brought under treatment.

Phosgene Poisoning.—In a paper read before the College of Physicians of Philadelphia, Dr. C. F. Hoover of Cleveland, Ohio, said that during the summer of 1917, in the Ypres region, a large number of men suffering from phosgene poisoning were brought into the casualty clearing stations of the British Service. To estimate properly the relative importance of each source for symptoms in these men it is necessary to make a clear differential analysis of the rôle each factor of distress is playing. Strictly speaking, inhalation of phosgene does not primarily cause poisoning, but inflicts a trauma on the respiratory path to which can be traced all the baneful results which follow. All the symptoms can be traced directly to impairment of external respiration by lesions of the respiratory membrane and its blood vessels and also to lesions of the tracheobronchial mucosa. If air laden with phosgene is inhaled, no phosgene can be found in the circulating blood; for directly phosgene comes in contact with moisture, hydrochloric acid is evolved. At the end of an inspiratory effort the respiratory air path is filled with air, but only in that part which lies beyond the bronchioles, viz., in the respiratory units, will there be sufficient moisture in the air to cause the evolution of hydrochloric acid. Should phosgene be inhaled a sufficiently long time, the moisture lying on the mucosa of the tracheobronchial tract will capture a sufficient amount of hydrochloric acid to produce an escharotic effect on its entire mucosa. The first effect from inhalation of phosgene is pulmonary edema. From this many patients die and at autopsy nothing can be detected, even by microscopic examination, beyond the filling of the alveolar cells with plasma. Pulmonary edema from this source differs from that which we ordinarily see in clinical practice, being equally distributed throughout the lung and independent of any diminution in the minute volume of blood passing through the lung; it is not preceded by air hunger, and the impairment of external respiration may result in death without the patient complaining of air hunger. Gray cyanosis without air hunger is due to anoxemia, i. e. diminished oxygen content of the blood unattended by an increase in the CO₂ content of the blood. Inhalation of oxygen will compensate for anoxemia, but the air hunger will be abrogated in these patients only by some method which will dispose of pulmonary edema. Superventilation and peribronchiolitis and endobronchiolitis are sources of pulmonary emphysema in phosgene poisoning. These cannot be regarded as a cause of air hunger. A third source of emphysema is general bronchiolar spasm. When bronchiolar spasm is added to the other causes of air hunger we see inspiratory narrowing of the subcostal angle and the entire costal margins of both sides are drawn toward the median line during inspiration. Adrenaline given hypodermically in doses of 20 minims of a 1:1000 solution will promptly relieve bronchiolar spasm and within one and a half minutes the entire costal margin on both sides will resume normal outward movements during inspiration. Unless the movements of the costal margins are observed, bronchiolar spasm will be overlooked because the great pulmonary edema

and air hunger will obscure any sign of respiratory distress due to the spasm.

A small number of patients developed symptoms dysenteric in character. Recovery from all systems, however, was very rapid. Hemorrhage in the central nervous system apparently occurred in only very severe cases. The only factor to which hemorrhages in the alimentary tract and central nervous system can be ascribed is anoxemia. Inhalation of oxygen will relieve the anoxemia and may thus prevent hemorrhagic lesions in the central nervous system. It is very important that medical officers understand the pathological physiology of phosgene poisoning; also to have information on a patient's field card, giving base hospital physicians a definite idea of the severity of symptoms developed immediately after inhalation of phosgene.

For the adequate study of the sequelæ of phosgene poisoning there must be evolved a method by which can be accurately estimated the partial pressure of CO_2 in both the effluent blood of the pulmonary circulation. Dr. Pearce of the Medical Service of Lakeside Hospital has thus far been partially successful in determining both these points, but the partial pressure of CO_2 in the effluent blood has not yet been satisfactorily estimated. There is now a patient at Lakeside Hospital who was "gassed" at Loos 18 months ago. He has a respiratory function which is very inadequate for exercise, but is quite sufficient when he is at rest. The heart and lungs are perfectly normal to all methods of physical examination, but when he exercises very moderately the partial pressure of CO_2 in his venous blood rapidly mounts.

The only other gas encountered in the Ypres region in the summer of 1917 was the blister gas, a name given through ignorance of its chemical formula. Like phosgene, it came over in shells and apparently caused only blisters on the skin and severe edema of the eyelids and the conjunctivæ. In many patients cardiorespiratory symptoms like those of phosgene poisoning were also present, but it is probable that they were suffering from both gases. Many of the men with the severest symptoms of blister gas were free of pulmonary symptoms. The blister gas penetrated the clothing and caused large bullæ over the body which were filled with firmly coagulated plasma. Delicate cutaneous structures like the prepuce and eyelids were enormously swollen from edema. Dr. Hoover saw no lesions of the cornea, and so far as he knew there were no visceral lesions from blister gas. Treatment consisted in the evacuation of the plasma and application of a dry aseptic dressing such as boracic acid powder; picric acid 1:1000 was also used. The eyes were treated by dropping into them adrenaline in 1:1000 solution and 10 per cent. argyrol. After the cutaneous lesions were healed the sites of the bullæ became brown pigmented areas. So far as the speaker was able to learn from medical officers there were no fatalities from blister gas.

eral Medical Board of the Council of National Defense held its regular meeting, which is usually held in Washington, at Camp Greenleaf, Chickamauga Park, Ga., on March 10, in connection with the dedication of the Warden McLean Auditorium, the main building of the military medical school at Camp Greenleaf. Beside the main assembly room this building contains a number of smaller rooms, including an orthopedic museum, a library and reference room, lecture rooms, study rooms, and office. Since the opening of the camp 4,000 officers and 20,000 enlisted men have been trained and sent to duty abroad or as instructors at other camps. Among those who made addresses at the dedication exercises were Dr. John C. Clark of Philadelphia, who made the speech of formal presentation of the \$10,000 auditorium; Surgeon General Gorgas, Brigadier-General J. B. Erwin, Lieutenant-Colonel Victor C. Vaughan, and Dr. Edward P. Davis of Philadelphia. Dr. Gorgas argued for the military training of medical officers. He stated that notwithstanding the handicaps, the present American Army had established a sanitary world's record, for it had cared for 1,000,000 men and the death rate was 10 men per thousand, whereas, Japan during the Russo-Japanese War, was deemed to have accomplished a marvel when she kept her death rate down to 20 per thousand. Camp Greenleaf will probably be the focus of the military medical activities of the country, as it is the geographic center of 450,000 troops in training.

At this meeting Dr. William H. Welch read a statement showing the statistical status of the Army and Navy in respect to the medical service. The men enrolled in the Medical Officers' Reserve Corps and recommended to the Adjutant-General's office totaled 21,824, of whom 17,313 have accepted their commissions. In the Dental Reserve Corps 5,086 have accepted commissions; in the Sanitary Corps, 865 have accepted. There are 844 officers in the Naval Medical Corps and 103 in the Naval Dental Corps. The total of officers available for active naval service is 2,257. In February there was an exceedingly satisfactory decline in the admission rates for communicable diseases in the camps and cantonments in this country. In the force afloat the situation as to pneumonia and cerebrospinal meningitis is very satisfactory. Scarlet fever has been more prevalent than usual but in no sense epidemic. There has been a very satisfactory decrease in measles, while mumps continues as heretofore. Surgeon-General Blue, who was unable to be present at the meeting, sent a communication urging that publicity be given to the fact that the Public Health Service is greatly in need of the services of competent sanitarians, particularly medical officers, sanitary engineers, and scientific assistants. The salaries of these positions range from \$1,800 to \$2,500 per annum. Applicants should address the Surgeon General of the United States Public Health Service, Washington, D. C. Surgeon Knight's report summarized the work done under his direction since September, 1917, in the five-mile zone around Chickamauga Park, a zone having 100,000 inhabitants. This work included a wide variety of sanitary and public health activities and may well serve as a

Dedication of the New Warden McLean Auditorium at Camp Greenleaf, Georgia.—The Gen-

model of the work that should be done in camp zones. Dr. William D. Haggard of Vanderbilt University presented a statement showing that there are 20 base hospitals on active duty abroad, 14 others mobilized, and 19 certified as ready for immediate service. Authority for Red Cross work within camps has been conferred by an official order signed by the Secretary of War. Twenty-seven units have cooperated with Federal and State authorities in February in 17 different States. Four laboratory cars have been turned over to the Army Medical Corps. Venereal clinics are now in operation in 17 camp cities. Major William F. Snow described the work that was being done by the Committee for Civilian Cooperation in Combating Venereal Diseases. Major Edward Martin, reporting for the Committee on State Activities, mentioned six manuals on medical military practice, all of which have been approved by the Surgeon General's Office. Dr. Charles H. Mayo, reporting for the Committee on Surgery, told how data on 21,000 physicians had been gathered and placed on cards convenient for ready selection of individuals and groups suited for any given task. He emphasized the need of reconstructing the wounded not only for field service, but also for labor after the war. He cited the many Government activities in which medicine entered and expressed the opinion that these could be coordinated in no way except by having a medical man as a cabinet officer. He also made a plea for adequate recognition and rank for medical men in the Government services. The report of the Nursing Committee indicates that the quota of nurses that are needed by June 1 will be provided. Dr. John D. McLean told of the progress of the plans for the Volunteer Medical Service Corps, which would be open to reputable physicians ineligible to the Medical Reserve Corps because they were over the age of 55, on account of physical disability, or because of necessity for home service. Emphasis was given the fact that this organization "will not protect slackers at home."

Casualties Among American Expeditionary Forces.—The casualties among the American Expeditionary Forces, as announced by the War Department, on March 22, number 2,066. Of this number 163 were killed in action, 149 by accident, 715 by disease, 237 were lost at sea, 11 committed suicide, 40 died of wounds, 14 of unknown causes, 6 were gassed, and 1 was executed. There have been 660 men wounded, 21 captured, and 39 missing.

Red Cross Aids in Rescue of Air Raid Victims.—Air-raid rescue service has become a part of the regular activities of the American Red Cross in Paris. Ambulances and rescue parties are on duty nightly and through cooperation with the police respond to all calls. The workers are equipped with gas masks and helmets. Not only do the Red Cross workers assist in transporting dead and wounded, but they assist the police and firemen in digging into the ruins and removing victims trapped in the buildings. It is reported that in one raid recently the Red Cross received five calls within an hour from as many widely separated points.

Convalescent Home for Government Service.—The convalescent home of the Burke Foundation has been offered to the Government for the period of the war, and arrangements are about completed for using this institution as a home for convalescent soldiers and sailors. The home will furnish accommodations for several hundred men.

Major Grayson M. P. Murphy has been awarded the first Liberty Service Medal, recently created by the American Social Science Association in recognition of notable humanitarian and patriotic services for national welfare.

Lieutenant H. R. Davies of the United States Medical Reserve Corps has received the Distinguished Service Cross, one of the four new American decorations for bravery. He remained in a dugout under continuous shell fire attending to the occupants after it had been blown in. He is the first American serving with the British forces upon whom this medal has been conferred.

Dr. Edward Wallace Lee, M. R. C., of New York, has been ordered to Porto Rico, to report to the commanding officer for assignment to duty.

Activities of the American Red Cross in France.—Totals of the American Red Cross in France in helping soldiers during the month of February, exclusive of civil affairs, show the following: Canteens in the metropolitan district supplied food and drink to 400,000 men. Fourteen traveling canteens at the front supplied 439,000 drinks, while seven canteens on the French lines of communication supplied 475,000 meals. The hospital supply service furnished 1,465 hospitals with 4,096 cases containing 257,863 articles. Distribution by the military supply company included in addition many thousands of articles of clothing for soldiers in the hospitals, among which were 199,000 pairs of flannel pajamas, 146,000 pairs of muslin pajamas, 130,000 pairs of socks, 51,000 shirts, and 1,040 cases, each containing 124 cartons of tobacco and cigarettes.

Hospital for Serbia.—The American Women's Hospitals, which is the official clearing house through which women doctors are sent abroad for Red Cross service, and which now has about fifty workers in the war zone, has acceded to an official request to furnish a base hospital for Serbian volunteers. It will also establish a chain of clinics and dispensaries throughout France and Italy. One-third of the funds of this organization are to be devoted to saving children in the devastated region.

New York Preparing Hospital Accommodations for Soldiers.—On March 26 an important hearing was held by the Committee on Hospital and Medical Facilities of the Mayor's Committee on National Defense for the purpose of planning coordination of medical facilities in the city to care for the tide of sick and wounded men returning to this port. The State Board of Charities will be requested to order at once a complete survey of hospital facilities of both city and State with a view to ascertaining their availability for military use. In this connection it is the intention in all cases where expansion of public or private hospitals is found necessary to make the extension permanent. It was brought out that there are now some 1,200 navy patients scattered among the various public and private institutions here.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, March 30, 1918.

PATHOLOGY WITHOUT INFECTION.

IT WAS Pasteur who prophesied that infectious maladies would eventually be banished from the earth. The first impression is that with infections banished there would be little left to engage the activities of medical men, as a result of which the profession, greatly cut down in numbers, would sink to a low level of influence. But an analysis of the subject shows that with the immediate and remote effects of infection abolished the activities of the profession would only be more or less modified and shifted about, while its influence would be enhanced. The pediatricist of the future would be able to devote most of his attention to problems of growth and development. Child psychology, pedagogics, the care of the defective and crippled, athletic training, the choice of a vocation, and other subjects now in the hands of special workers would all be centralized in the training of one body of men, and no pediatricist could afford to remain in ignorance of any branch of knowledge which affects the welfare of the child and young adolescent.

Curiously enough, obstetrics would go on with relatively slight changes. The great problems of dystocia would still remain, and the whole of operative midwifery would therefore continue to demand the attention of the highly-trained man. So far as can be foreseen, this conservatism would also inhere in the toxicoses of pregnancy and in most of the morbidity of the newly born, which is of developmental nature. On the other hand, gynecology would shrink enormously in the absence of infections, and might come to be a mere appanage of obstetrics; for most of the work to be done would consist of repairing the ravages of dystocic labors. In all likelihood, however, major gynecology would class with general abdominal and pelvic surgery, which is the trend at the present time.

Abdominal surgery, greatly narrowed as a result of the abolition of infection, would retain some of its present character in the direction of intestinal obstruction, including hernia. There would still be sterile adhesions to deal with. Traumatisms would also demand highly trained men for laparotomy. Operations for various ptoses, especially float-

ing kidney, would go on as before. The elimination of infection would enlarge the scope of laparotomy, and it is possible that many a case of dysmenorrhea and sterility would come to be relieved by simple interventions. In all probability, operations for myomatous uteri would be performed with the old frequency. Surgery of the other body cavities and extremities would be overwhelmingly traumatic, although many decompression operations would be required for non-traumatic affections, and much plastic and orthopedic work would have to be done for developmental and other anomalies. The great problems of shock, hemorrhage, and anesthesia would persist in undiminished importance, and this fact alone teaches that the surgeon must remain a leading figure among superior men, and would not degenerate into a glorified mechanic.

In a non-infectious world the internist would find his activities modified in much the same way as those of the pediatricist. He would become a toxicologist in the widest sense of the term, and have much greater knowledge than at present of the effects of occupation and habits on the health. As the problems of childhood have to do with growth and development in their widest ramifications, so in adult life the diseases of occupation spring into prominence along with the evils due to bad habits. The general physician would need much more than a smattering of dietetics and the specialty of gastroenterology might disappear along with some of the others of its kind. The separation between the internist and neurologist would perhaps no longer exist. The internist would be the diagnostician *par excellence*, and would always be in demand for insurance and other examinations, and for forensic work. The internist would also turn his attention to the ailments of the aging and aged man, and would have a great field in life extension work.

The moral of this sort of forecast is that it does not bear on the remote future alone, but on the near future, and even on present-day conditions. It shows us certain trends in the evolution of medicine which can be realized during the lifetime of men now living, and which, since they point out shortcomings in medical practice to-day, should be hastened at once.

SOUND APPRECIATION IN MEDICAL DIAGNOSIS.

SENSORY acuity and patency of the senses generally are the factors that connect the organism, specifically the brain centers, with stimuli from the outside. It is by reason of these constant stimuli, from the inception of life to death, that the brain develops. The rapidity and completeness of development, so to say, as well as the efficiency of the individual, depend upon the acuity of the senses which transmit these stimuli from the outside. Indeed, we appreciate extrinsic conditions only in accordance with the acuity of our senses, governed always, of course, by the ability of the nervous centers to

receive them and to co-ordinate them with sense stimuli transmitted by other senses. No sense really acts by itself. A defect in one sense affects the others, unless there is either the much doubted natural compensation, or a compensation from greater attention to other senses. Granted the inherent patency of the senses, they can operate to their full capacity only after training. Poor senses, well trained, may be better than good senses receiving no training. There may also be a natural hypertrophy of some senses, as in musicians, painters, mechanics, etc. Aside from the manual ability of a musician to play musical instruments, a good musician is an individual in whom the sense of hearing—that is, the internal appreciation of sound, the tone sense—is highly developed in the hearing centers of the brain. Every one has some of this tone sense, which can be developed within limits.

In medical diagnoses the part that sounds play is very important. Not only do the sounds heard on auscultation or percussion betray the diagnosis, but the fine differences between diseases of the same types are diagnosed by appreciating sound differences. Often appreciation of the sounds in cardiac diseases gives a clue to prognosis. The appreciation of the presence of adventitious sounds merely is not sufficient to make a diagnosis. Many adventitious sounds have no pathological significance of themselves unless they assume certain tone characteristics. The diagnosis of heart conditions, as well as pulmonary diseases, often requires the most acute appreciation of sound differences. Intensity, pitch, rhythm, and duration are qualities of sound that are always before the diagnostician almost as much as before the musician. It does not follow, of course, that a good musician would make a good diagnostician, because the diagnostician must have other senses developed to a high degree, and possess other qualities just as indispensable as the tone sense. While the musician is a tone specialist, the physician must be more versatile in his sense development. Yet the necessity of a general musical education cannot be overestimated, for many reasons, but particularly because of the development of the tone sense, which otherwise is too often neglected. For those contemplating a medical education this necessity is particularly trenchant. One whose sense of sound appreciation is dull or undeveloped, or who is tone deaf, cannot make a competent diagnostician. The more refined auscultatory diagnoses can be made only by one with a refined tone sense. Gross sounds are appreciated by every one; the finer tones must have a special ear, so to say.

It is not implied that one who has not a refined acoustic sense cannot do medical work, but one does better and more specialized work with it. An appreciation by the physician of the condition of this or other senses will help him determine what specialty in medicine he can do best. No one who is not motor-minded should undertake surgical technique, nor should one who has poor vision under-

take refraction or other eye work. Not only is there an acute necessity for understanding every individual's vocational adaptabilities, but where a vocation allows of specialization, physical or sensory adaptations must be understood before a decision is made; otherwise, many incompetents will be created.

THE DIGESTIVE DISTURBANCES OF AZOTEMIA.

It is difficult enough to teach beginners in medicine how to recognize the presence of interstitial nephritis in its earlier stages, and Dr. Alfred Loomis, perhaps because it was necessary to say something definite to students, used to lay great stress on the presence of unmotivated digestive disturbances. Laufer, a French army physician, writing in the *Bulletin Général de Thérapeutique* for January, 1918, states that one-fourth of all patients referred to him for gastroenteric disturbances were found to have renal insufficiency. The chief of these disturbances were clinical diarrheas, gastroenteritides, and acute indigestion, and in a lesser degree "dyspepsia" without further qualification. Despite the real nature of these disturbances, they are curable, but only through regulation of diet to antagonize the azotemia. The purest alimentary expression of the latter is a bland abundant serous diarrhea—apparently an effort of nature to eliminate the excess of urea. With this diarrhea there may or may not be nausea or vomiting, also unmotivated, and of the same serous type. The vomiting may be incessant and the vomitus, like the stools, contain a definite percentage of urea. But phenomena of this character indicate major uremia and are accompanied by other evidences of the latter.

Of a different character are the enteritis and colitis associated with a low degree of azotemia. Of 108 cases of these conditions, 28 were found to have this motivation. Such patients complain of the so-called minor uremic or preuremic symptoms, and the entire picture may benefit by cutting down the nitrogen in the diet. Of great interest are the so-called dyspeptic cases, because no evidences of renal insufficiency may be at hand. There is a host of symptoms which come under the head of indigestion, and the patients are usually pale and emaciated. If the urine is examined albumin will be absent in over one-half of the cases. The diagnosis may be carcinoma or nervous indigestion; and only a blood examination will reveal the true cause—increased urea. Naturally such cases yield to diet. In epidemic affections in which the patients have some renal insufficiency—dysentery in one of its forms, for example,—the azotemia will modify the symptoms. A form of biliousness, so called, may be traceable to azotemia. Conditions are quite possible in which the renal lesion may be secondary to, or may have the same causation as, an infectious enteritis.

NEPHRITIS ACUTA BELLI.

UNDER this caption Ceconi considers (*Riforma medica*, January 26) the somewhat trite subject of war nephritis. He gives first an historical outline in which he states the arguments in favor of the infectious nature of the malady. This is followed by a consideration of the clinical phenomena and nosology. The factors of cold, tonsillar infection, and acute articular rheumatism are especially considered. Finally, the part played in causation by the spirochete and the rickettsia is discussed, along with the possibility of louse transmission and of the possible relationship between war nephritis, on the one hand, and typhus, febris recurrens, and Volhynia fever, on the other. Ceconi finds that the explanation as to the nature of these nephritides, as they are found in current literature, is not warranted. He is inclined to think that we have here in part a malady which is specific and *sui generis*—in other words, a new or hitherto undescribed disease. That is to say, it is new in Italy and the other European countries with the possible exception of Russia. There is some reason to believe that in the latter it occurred before the war—in other words, among a civilian population, and, as sometimes happens, the war has brought to light the existence of an old but unrecognized malady. Naturally the existence of this masked malady does not exhaust the subject of war nephritis. There is even some reason for the belief that epidemic nephritis has occurred in previous wars.

The Teutonic literature of this affection is much larger than that of the other countries, and one of the most original and convincing writers on the subject is Toepfer, who has seen in German troops on the Eastern front and in Russian prisoners epidemics of nephritis and edema which are assuredly of infectious nature. He accumulated evidence to show that in both affections the louse was active in transmitting the disease; further, he succeeded in isolating a microorganism from the stomach contents of the louse; and finally a vigorous antilouse campaign appeared to check the incidence of the two diseases. The same parasite, in other words, was accused of causing epidemic edema and war nephritis. Morphologically, the accused bacillus is not new, for it appears to answer to an organism which at various times has been accused of causing both typhus and Volhynia fever. At present the question must be left at this stage of development until Toepfer's finds can be corroborated or disproved.

THE HISTORY OF THE X-RAY.

SINCE the beginning of the war the statement has been made frequently that while the German scientific men rightly hold a high place in the world of science they do not reach that altitude which they are accustomed to arrogate to themselves. They appear to be decidedly sterile of original ideas, but excel in painstaking research. They develop

discoveries rather than initiate them. In short, what they lack in brilliancy they make up in persistency. An example of this want of originality, but instinct for making use of the discoveries of others is excellently illustrated in a paper published in the *Western Medical Times*, March, 1918, contributed by Dr. Douglas H. Stewart of New York, who shows that, contrary to common belief, Roentgen did not discover the x-ray. Dr. J. Belot of Paris wrote a work upon Radiotherapy in Dermatology, which contained an historical review of Roentgen's discovery. According to this work, the Abbé Nollet, in the eighteenth century, was the first to devise an apparatus which in principle was the same as that employed at the present day for the production of x-rays. The Crookes tube is a further development of the same principle, but it was Lenard, in 1893, who first observed the x-rays which Roentgen utilized for photographic purposes. Thus Lenard was the discoverer, Roentgen the utilizer for photographic purposes, and Schiff and Freund the employers for therapeutic purposes. Dr. Stewart also points out that Americans seem to be unaware of the enormous amount of experimentation and writing upon Roentgenology that Paris and its publications afford. Unfortunately, the French scientists write only for those who read French, and it is but rarely that a translation is made into English; whereas translations into German abound, and many Germans read French. The consequence of this is that Americans often refer to scientific matters as being of German origin when they have but reached us through German sources.

VENTILATION AND CEREBROSPINAL FEVER.

CEREBROSPINAL meningitis is by no means easy to diagnose correctly in its early stages because it simulates in many of its symptoms other diseases, and especially grippe. As Capt. J. C. McWalter says in the *Medical Press and Circular* for February 6, 1918, no practitioner is so stupid as to be unable to spot a case when well developed and when the disorder is known to be rife, and no man is so competent as not to be deceived in the earlier days of the disorder, more particularly if influenza, with myalgia of the spinal muscles, is prevalent. Cerebrospinal meningitis is a disease which deserves special consideration at the present time, because it seems to be connected with overcrowding and moist heat. It has occurred in camps in this country and unless great care is exercised is apt to break out at any time. McWalter points out that the ordinary form of temporary wooden hut adopted in most of the British camps is by no means free from suspicion. These huts are not only overcrowded, but insufficiently and inadequately ventilated. In addition, for the sake of warmth, the stove pipe is carried right up to the roof inside the hut. The hut is warm, and a certain amount of carbon monoxide is given off; towels, socks, and handkerchiefs are hung up to dry in the heated air. If any of the inmates have catarrh, influenza, pharyngitis, or cerebrospinal organisms, ideal conditions are furnished for the development, intensification, or propagation of the disease. Similar conditions have prevailed in some of our cantonments in this country. In huts and barracks of

this description, of which the ventilation is inadequate, conditions are most favorable for the development and spread of cerebrospinal fever. Our army medical authorities should insist that in the camps in France and here the huts should not be overcrowded, or, at any rate, should be well ventilated and kept as clean as possible. But unfortunately the medical officers have little influence so long as their recommendations must be made to their superior officers, who may or may not suppress them according as they do or do not have faith in modern sanitary methods. Many of them have not, just as the many ignorant persons in civil life have not.

News of the Week.

Vaccination and Tetanus.—The *Monthly Bulletin* of the New York State Department of Health for March is a "Smallpox Number." It shows the extent to which smallpox has been prevalent in the State and emphasizes the value of vaccination as a protection against smallpox. In refutation of the statement frequently made that vaccination produces tetanus, a list of the deaths caused by tetanus in New York State, in 1917, is given. This shows that of 49 deaths in the State due to tetanus during 1917, 10 resulted from the infection of lacerations and abrasions, 9 from incised wounds, 8 from infection at childbirth, 5 from compound fractures and dislocations, 6 through infected surfaces and from various other conditions, but one from vaccination. In this case death occurred 40 days after the child was vaccinated and all the evidence goes to show that the vaccine itself was not the cause of death. During the year 1917 reports of nearly 50,000 vaccinations have been filed with the State Department of Health and in only one case out of this entire number did a death occur that had the slightest connection with vaccination. Dr. John F. Anderson, in 1915, reported that out of 31,000,000 doses of vaccine virus used in the United States there were only 41 authenticated cases of tetanus subsequent to vaccination. Out of about 585,000 vaccinations done in the United States army and navy there was not a single instance of tetanus following the operation.

Grip Epidemic in New York.—Though influenza is not a reportable disease and there are no figures to show the extent of the present epidemic, it is said that not since 1889-90 has this disease cut so heavily into the working forces of large employers of labor, both in office and shop, as it is doing at present. The Health Department has given out a list of precautions with a warning that grip is the most easily transmitted of all the highly contagious respiratory diseases, and that it is advisable to avoid crowds and badly ventilated apartments. The prevalence of grip in Sing Sing prison has caused the suspension of all business and amusements to prevent the spread of the disease. On March 23 there were 30 patients suffering from grip in the prison hospital and 70 more ill in the dormitory and cell block.

Illiteracy in New York.—There are two bills before the Legislature of New York aimed to enforce

compulsory education on the foreign born. One of these bills requires attendance at either day or night school of every non-English-speaking and illiterate minor in the State and provides a penalty. The second bill makes it compulsory for boards of education to provide night schools in any school district where there are twenty or more illiterate minors. The necessity for these bills is shown by the fact that there are in New York State 2,729,272 foreign born 597,012 non-English-speaking, and 362,025 illiterates, the percentage of illiteracy being 13.7.

Public Nurses for Rural Districts.—A bill has been introduced into the Legislature of New York which provides for public nurses in rural districts. This measure would authorize one graduate nurse for every 15,000 of population in each county exclusive of the inhabitants of cities. The nurses would receive salaries of \$1,200 a year, and the boards of supervisors would be expected to furnish the funds.

Germany Plans Policy for Repopulation.—Although Germany's vital statistics are not being published broadcast during the period of the war a recent communication has reached this country giving fairly accurate estimates of the birth rates of cities and towns of more than 15,000 inhabitants. These go to show that the birth rate of Germany has been cut nearly in half since the beginning of the war. At the same time a report from Washington states that statistics recently read in the Hungarian Chamber of Deputies shows the same rate of decline in the birth rate of Austro-Hungary. This report further states that in peace time the infant mortality rate of that country was about 34 per cent. and that in 1916 it had risen to 50 per cent. In Germany the population problem is to be attacked by the State aiding the two general lines of "increasing production" and "conservation." The policy is to include, according to this report, legislation against aiding and abetting voluntary race suicide; economic favoritism to large families; improvement in the housing condition of the poor; extensive colonization of the city population in the agricultural provinces; premiums on children to small salaried State officials; a campaign against infant mortality; extension of social welfare work; the reform of the midwife profession; compulsory courses of instruction in infant rearing for all girls in the public schools; the training of a large army of municipal child nurses, and improving the condition of illegitimate children.

Gifts and Bequests.—Under the will of Ludwig Dreyfus gifts amounting to more than \$1,000,000 are made to Jewish Charities. Among these bequests are the following: Mount Sinai Hospital, New York, \$37,500; Montefiore Home, \$37,000; Hebrew Benevolent and Orphan Asylum, \$27,500; Home for Aged and Infirm Hebrews, \$17,000; Beth Israel Hospital, \$12,500; German Hospital, \$5,500; the Hebrew Infant Asylum, \$5,000; the National Jewish Hospital in Denver, \$3,500. The Hospital for Deformities and Joint Diseases, Tuberculosis Prevention for Children, and the New York Eye and Ear Infirmary, each \$2,500; the Jewish Hospital, Brooklyn, \$1,000.

By the will of the late Sarah A. Rulens of Philadelphia, bequests are made as follows: Pennsylvania State Hospital for the Insane at Norristown, Pa., \$500; St. Christopher's Hospital for Children, \$400; Home of the Merciful Saviour for Crippled Children and Kensington Hospital for Women, each \$100.

By the will of the late Aaron L. Lowenstein of Philadelphia bequests are made as follows: Jewish Hospital, Mt. Sinai Hospital, each \$2,500; Jewish Maternity, Wills Eye Hospital, each \$1,000.

The Neurological Bulletin is the name of a new monthly journal published under the auspices of Columbia University by Paul B. Hoeber in New York City. The editor is Dr. Frederick Tilney, Professor of Nervous Diseases in the Medical Department of Columbia University, and the associate editor is Dr. Louis Casamajor. The first two numbers, for January and February, have appeared and contain much valuable material gathered from the weekly clinical conferences of the Neurological Department of the College of Physicians and Surgeons. There is a great wealth of material in this department which is worthy of permanent record and neurologists generally will welcome this journal which, while the most recently established, promises soon to be among the leaders in neurological literature.

New Aid for Child Welfare Work.—The Child Welfare Board of the General Medical Board of the Council of National Defense, of which Dr. Samuel McC. Hamill is chairman, has begun a movement to provide infant welfare stations in all parts of the country. The committee is going to cooperate with state, municipal, and county departments of health in order to increase the efficiency of their work. The attention of communities will be called to the effect of war in reducing the population and to the importance of preserving the lives of infants and children. Provision will be made for giving instruction in antenatal care as well as in the care of infants and of children of pre-school age. The plan includes propaganda urging that financial provision be made to enable a mother to stay at home and give proper care to her children.

The Death Rate of New York State in 1917.—The preliminary report of the State Health Commissioner, Dr. Herman M. Biggs, shows that the general death rate of the State for 1917 was 14.6 per thousand population, as against a rate of 14.7 for 1916, and an average for the previous five years of 14.9. It is only slightly higher than the 1915 rate, 14.5, which was the lowest rate recorded in the history of the State. The report calls attention to increasing mortalities from a number of causes. In certain localities the death rates were higher in 1917 than for several years. There was a total of 12,000 deaths from pneumonia, the highest recorded in the State since 1917. There was also an increased mortality from organic diseases of the heart and kidneys and from cancer. There were during the year 8,600 deaths from accidents. Automobile accidents were responsible for more deaths than typhoid fever, scarlet fever, and polimyelitis combined.

War Time Economies.—A meeting will be held in the New York Academy of Medicine under the

auspices of the Health and Hospital Committee of the National War Savings Committee, on Wednesday, April 3, 1918. Prof. Edwin R. A. Seligman will read a paper on "Common Economic Fallacies of the Average Man"; Dr. S. S. Goldwater on "Economy from the Hospital Standpoint," and Mr. George W. Wickersham on the "Financing of the War and War Savings Societies."

Obituary Notes.—Dr. DAVID PENFIELD AUSTIN, who had practised medicine in New York City for fifty-five years, died of injuries received as the result of a fall downstairs in his home, on March 21, aged 83 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1866.

Dr. JOHN GEORGE BLAKE, one of the oldest physicians of Boston, a friend of Oliver Wendell Holmes, and a surgeon in the Civil War, died at his home, on March 5, aged 81 years. He was a graduate of the Harvard Medical School, in 1861, and was attached to the staff of the Boston City and the Massachusetts General Hospitals. He served on the Boston School Board for sixteen consecutive years, and as a member of the water board for a time.

Dr. A. HAMILTON LEVINGS, a graduate of the Medical Department of the Northwestern University, in 1872, died at his home in Milwaukee, after a lingering illness, on March 4, aged 70 years. Dr. Levings spent considerable time in study abroad, organized the Wisconsin College of Physicians and Surgeons, and served for twenty years as its president; he served for a like period as professor of the principles and practice of surgery. In 1914 Dr. Levings organized the Wisconsin Surgical Association, and was the first president of this society. He was the author of two books, one an exhaustive work on "Tumors," and the other "Every-Day Surgery."

Dr. PETER BAKKA, formerly of Minneapolis, and more recently of Grantsburg, Wis., died at St. Luke's Hospital, in the latter town, on February 28, aged 53 years. He was a graduate of the University of Minnesota in 1892.

Dr. WILLIAM J. NICKERSON died of apoplexy at his home in New Bedford, Mass., on March 6, aged 73 years. He was a graduate of the Medical Department of Bowdoin College, in 1870, and a Civil War veteran, having been one of Gibbon's men who withstood Pickett's famous charge at Gettysburg.

Dr. JOHN ROBINSON GILDERSLEEVE, a graduate of the Medical Department of the University of Virginia, in 1862, and a surgeon in the Confederate Army, died suddenly of heart disease, in Richmond, Va., on March 5, aged 75 years.

Dr. JONATHAN M. CHENEY, a graduate of the University of Vermont Medical College, in 1887, died at his home in Ashland, N. H., on March 4, aged 55 years. At the time of his death he was a member of the Grafton County Medical Advisory Board.

Dr. GEORGE A. WHITE of Sacramento, Cal., died in a local hospital on March 2, aged 70 years. He was a graduate of Jefferson Medical College in 1870.

Dr. SEABURY W. BOWEN, a graduate of Bellevue Hospital Medical College, in 1867, and a member of the staff of the Fall River Hospital since its origin, died at his home in Fall River on March 3, aged 78 years.

Dr. JAMES EMMETT CONN, a graduate of the State

University of Iowa, and a founder of the Conn Hospital of Ida Grove, Iowa, died suddenly at his home in that town, on March 2, aged 51 years.

Dr. E. VALENTINE BUCK, a graduate of New York University Medical Department, in 1872, died at his home in New York City on March 16, aged 75 years.

Dr. JOHN A. RONAYNE of Astoria, L. I., a graduate of the College of Physicians and Surgeons, in 1896, died of pneumonia in the Polyclinic Hospital, New York, on March 18, aged 44 years.

Dr. WILLIAM LEE HOWARD of Westboro, Mass., a graduate of the University of Vermont, in 1890, died in the Waltham Hospital, on March 10, aged 57 years. Dr. Howard was a newspaper man in his earlier life, and was sent by the New York *Herald* on the relief party which went to rescue the Jeanette, which sailed from San Francisco in 1879 to find the North Pole. He was also well known on account of his writings on sex problems.

Dr. WILLIAM T. GLEASON of Ely, Nev., a first lieutenant in the Forty-third Infantry, assigned to Fort Douglas, died suddenly while on a furlough at Salt Lake City, on March 7, aged 39 years. He was a graduate of Rush Medical College, Chicago, in 1902.

Dr. JOHN W. COSTOLO, a graduate of the Physio-Medical College, Cincinnati, died at his home in Lima, Ohio, on March 7, aged 66 years.

Dr. GEORGE W. CURFMAN of Denver, Col., died in St. Luke's Hospital of a complication of diseases, on March 8, aged 41 years. He was a graduate of the Northwestern Medical College in 1905, and medical examiner of the Burlington Railroad.

Dr. AZUBA DOTY KING, a graduate of the State University of Iowa Medical College in 1876, died at her home in Des Moines, Iowa, on March 4, aged 82 years.

Dr. JOSE L. HIRSH, a well-known children's specialist of Baltimore, died suddenly of heart disease at his home, on March 17, aged 46 years. He was a graduate of the University of Maryland Medical College in 1895.

Dr. WILLIAM E. WAGNER of Philadelphia died, after a brief illness, in a New York Hospital, on March 17, aged 40 years. He was a graduate of Jefferson Medical College in 1906.

Dr. SARAH R. MEAD of Newark, N. J., a graduate of the Women's Medical College of the New York Infirmary, in 1883, died of injuries sustained in an automobile accident, in the Mountainside Hospital, Glen Ridge, N. J., on March 17.

Dr. READ JENNINGS MCKAY died at Wilmington, Del., on February 28, at the age of 75 years. He was graduated from Bellevue Hospital Medical College in the class of 1867.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE BELGIAN DOCTORS' AND PHARMACISTS' RELIEF FUND—RATIONING OF LONDON.

LONDON, March 2, 1918.

THE Belgian Doctors' and Pharmacists' Relief fund made its first appeal to the doctors and pharmacists of the British Empire on November 21,

1914. The response was instantaneous and generous. By April, 1915, the Executive Committee received over £10,000—a total which steadily increased until at the end of 1917 the donations amounted to just £20,000. Towards this large sum of money the Colonies helped largely, Canada subscribing £2,248, Australasia £2,423, New Zealand £1,638, South Africa £96, and in addition to these sums India sent £250, Denmark £290, and Italy £56. Certain subscriptions were received from two sources in the United States, but it was well understood that the enormous amount of aid in money and kind, poured into Belgium from the United States, had a great part in relieving the stress on doctors and pharmacists. The money received was discreetly invested, the fund earning during distribution over £1,000. Only £90 have been spent by the committee in administering the fund.

In the early days of the fund the expenditure consisted chiefly of small amounts given to relieve necessity among the refugee doctors and pharmacists in England, and of registration fees for those Belgian doctors who were anxious to obtain work in England or the British colonies, and who subsequently did so. But the amount spent in England has been relatively small, only £610. In March, 1915, £800 was sent to Belgium through the Commission for Relief in Belgium then magnificently administered by Mr. Herbert Hoover, whose work in the United States is now of world importance. Distribution in Belgium is for the present in the hands of Spanish and Dutch representatives.

In June, 1915, another £800 was sent and in July £400, but in April, 1916, powerful representations were made to the fund that regular assistance should be given as the need in Belgium had become so acute. The committee thereupon decided to send £800 every month to Belgium so long as the urgency lasted. The Commission for Relief in Belgium have forwarded this money every month to a trustworthy Belgian committee in Brussels and have vouched for the care of administration and the inestimable comfort which it has brought. For twenty months, from April, 1916, to November, 1917, the monthly check was sent, or a total of £16,000, but in December, 1917, the fund being by this time almost exhausted, the committee decided with the greatest possible regret that they could only send £700, whilst in February and March it was practicable to send only £400. Realizing that unless prompt and generous help was forthcoming the support given in the past to colleagues in Belgium must cease, the fund has issued a stirring appeal to which responses are coming in fairly well. The Belgian doctors and pharmacists are in many ways more in need of help now than they were at the beginning of the war; life does not become easier or German hearts softer, and in most cases the money sent only saves those who receive it from the direst want. In support of that second appeal a powerful letter has been circulated from Mr. W. B. Poland, the present director in Europe of the Commission for Relief in Belgium in succession to Mr. Hoover, in which it is shown that the money sent by the fund reaches its destination and effects wonderful good.

Subscriptions to the fund should be sent to the treasurer of the fund, Dr. H. A. Des Voeux, 14,

Buckingham Gate, London, S.W. In response to the suggestion of subscribers a system of monthly subscription has been inaugurated, and if well supported this would prove a solution of immediate and pressing difficulties.

The officers of the fund are: Sir Rickman J. Godlee, chairman; Dr. H. A. Des Voeux, honorary treasurer; Dr. S. Squire Sprigge, editor of *The Lancet*, and Mr. W. J. Uglow Woolcock, secretary of the Pharmaceutical Society of Great Britain, honorary secretaries. It is sincerely hoped by the officials of the fund that its work will be maintained, while they consider that the raising of so large a sum of money entirely among doctors and pharmacists forms a high tribute to professional generosity.

The rationing scheme which came into force for London and the adjoining counties in the last week in February is in the nature of an experiment. Admittedly the restrictions in several directions are more drastic than circumstances necessitated, but Lord Rhondda, the Minister of Food, has proved himself before now to be a tactful manager of men, and it is clear that relaxations are easy enough to make, while additional severity might be received with great disappointment if the circumstances could not be explained. And for yet another reason the rationing scheme for London and the Home Counties was devised on a Spartan plan; the scheme will certainly be used as a pattern to be followed by other counties or groups of counties, if and when necessity arises, and it might be that local factors called for temporary privations of a sharper sort in some places than in others, while it is clear that regulations should be uniform. All medical men and those acquainted with the real physiological value of food know that the ration contains everything that is necessary for the complete health of the working or sedentary man and woman. And this fact has been more widely recognized by the public than could have been anticipated by the medical profession, well used to the pathological conditions of patients a large mass of whom regularly eat and drink more than their physiological needs. The scheme, moreover, takes full note of the difficulties which might be brought about in the care of children and the sick, in which directions considerable flexibility is permitted. Not only is it decreed that expectant and nursing mothers and infants under 18 months of age shall have a prior claim upon the milk supply and shall obtain a definite amount, but all children under five years of age enjoy a similar privilege, while children of ten and upwards are counted as adults in the matter of meat supply. Attention has, however, been called by medical men to the gap that occurs in the diet of children between five and ten. Before the lower age they receive an adequate amount of milk and after the higher age a good quantity of meat is allowed to them out of regard for the special needs of growth. But between 5 and 10 the protein income of children runs a risk of being inadequate, and yet around the age of eight there is reason to suppose that children have a particular liability to nutritional disturbances. Evidence in their direction is supplied by the Elementary Educational Committee of the London County Council whose numerical responsibility towards the child life of

London is immense, having regard to the population of the county, about four and one-half millions. This committee has analyzed the results of the medical inspection of the children in the county schools up to 1917, and the information given by the report is in the highest degree satisfactory from the medical point of view. The war has not in any way affected the physique of the child population of London. On the contrary, it would seem that the steady employment at high wages of the majority of parents, by conducing to the better clothing and feeding of their offspring, has brought in material form benefits to the children. It may be said that this occurred before the rationing scheme came into force and that the value of the information is by this much discounted. This is not the case. Throughout the whole of 1917 a fairly drastic scheme of voluntary rationing was followed by many conscientious persons, while the bad distribution of food, as well as the shortage in certain commodities, produced all round a standard of diet not only lower than that before the war or during the first two years of the war, but not very far above the standard now dictated by legal rationing. The affect of privation or disease consequent upon the war, as seen among growing children, does not therefore in the case of London children seem to be at all marked, but the report does suggest that the eight-year-old children are especially prone to defaults in nutrition and that the gap which I have indicated above in the legal rationing of these children ought to be filled at an early date. There will, it is believed, be no difficulty in accomplishing this, as a surplus of meat may now be foretold.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

RED CROSS TO CARE FOR PRISONERS—PRESENT WORK FOR REFUGEES, AND OTHER ACTIVITIES—PHYSICAL TRAINING IN THE ARMY—JIU-JITSU IMPRACTICABLE—ACTIVITY OF THE Y. M. C. A.

PARIS, February 25, 1918.

THE American Red Cross has been designated in an army order as a distributing agent of supplies to "American soldiers and others who may be prisoners in the hands of any power with which the United States may at any time be at war." The American Red Cross Central Bureau for American Prisoners is the name of the service which has this work in hand. It has an office in Berne, and has established an excellent warehouse. Parcels are made up by a system adopted by the British, and supplies are shipped direct from America to the Red Cross warehouse.

At the present time there are only a few prisoners held in Germany, but the Red Cross warehouse staff has made arrangements for the future, and as prisoners increase in numbers they will be provided for. Each prisoner receives a request to acknowledge his parcel, and by using the methods found effective by our British allies the Red Cross is able to insure the safe arrival of goods sent to prisoners. The importance of sending parcels to prisoner camps need not to be insisted upon. Indeed, through this bureau the American fighter taken prisoner will receive supplies of food and clothing making the prison camp bearable.

The Bureau of Refugees and Relief of the American Red Cross has completed arrangements to work in the care and relief of refugees and repatriated French arriving from Germany in conjunction with the French Red Cross. One thousand refugees are evacuated daily into France by the Germans. Either because they are too old, too young, or their infirmities render them useless, the Germans regard them as just so many mouths to feed, and so, when they cannot work, they are sent back to the French.

Dr. Edward T. Devine is in charge of the Bureau for the Relief of Refugees, and he has established his headquarters at Toulon, the great furniture center of France. He has thirty delegates, who work through the prefect or the mayor, scattered through the south of France, where the refugees are sent. Sometimes money is given to the refugees if they really need it, but it is not usual, and the American Red Cross prefers to help them in other ways. The French Government grants refugees a certain sum of money, sufficient to meet their daily needs, and the American Red Cross furnishes their temporary homes for them. Contracts for several tens of thousands sets of furniture have been placed by the American Red Cross with furniture makers at Toulon. When the refugees have a little money of their own they are expected to pay the American Red Cross on the installment plan. When, however, they are not in a position to pay the furniture is given to them for nothing.

The American Red Cross also helps the refugees by establishing dispensaries and hospitals where they are given special treatment. It must be remembered that all the people lucky enough to be sent back are human wrecks, and many of them have reached the advanced stages of tuberculosis. The French refugees have learned to appreciate the work that the American Red Cross has done for them. In many cases it was the American Red Cross that helped them when they were captives, and then when they are free it is the American Red Cross again that attends to them. The French Red Cross and the American Red Cross are working together in perfect harmony, and in many cases the Bureau of Refugees works directly through the French Red Cross.

Five of the Red Cross recreation huts are now in operation at base hospitals. While all of the equipment has not been installed in some of the huts the programs and activities planned for these places are going forward. While waiting for the completion of construction work on huts at other hospitals rooms have been found that enable the Red Cross and Y. M. C. A. to carry on their recreational activities in temporary quarters.

At one of the base hospitals the American Red Cross representative is acting as chairman of a committee to organize and operate a civilian hospital for the benefit of the people in the village. An old school building, adaptable for the purpose, has been leased. It is designed to supply ten or twelve beds, which will suffice for local needs. The Red Cross will contribute 1,000 francs a month toward the support of the hospital. A personal gift of \$500 has been made toward the hospital fund by a friend of the officer in charge of the base hospital.

The transportation department of the American

Red Cross now has more than 500 automobile vehicles of all kinds in operation. During the past month they moved more than 3,600 tons of materials. The total amount of Red Cross rail shipments during January was approximately 8,400 tons.

Considerable discussion has sprung up respecting the physical training of our troops in France, and a persistent effort is being made to secure the introduction of jiu-jitsu into the training exercises. At first it might seem rather puerile to indulge in so much discussion over this particular exercise, but when the facts are disclosed they throw a light that changes the point of view.

The personal hatred of the Hun for the English is much talked of in print, but is only known in its full significance to those close to the scene of action. The rushing and taking of trenches is hardly ever without its incidents of personal encounter where the closeness of contact precludes the employment of arms and locked in each other's death grip, fingers, nails, and teeth form the weapons of offense. We are well aware of the fact that next to the deadly hatred for the English the Americans come second and there is an undoubted advantage attached to the German side whose troops have been seasoned and hardened by three years of warfare. There is, therefore, a feeling of insistence that anything that promises any new tricks that can give us advantage over the adversary should not be neglected and that is the sentiment that is behind the discussion of jiu-jitsu.

Dr. Luther H. Gulick, who was the first organizing secretary of the Y. M. C. A. in the United States and Canada and had 100,000 of our boys organized into the first Army Athletic League, expressed considerable scepticism regarding the value of this procedure. He said that in the United States they had tried their best to find some representative jiu-jitsu man who would meet their best man on fair conditions to each side, but had met with little success. He had never seen a jiu-jitsu man come out against a trained American in American clothes and without any obligation to the restrictions of Japanese rules.

Mr. G. R. Mills, when interviewed upon the subject, said that the introduction of jiu-jitsu into the American Army as a method of training men probably would fall far short of success as measured by present standards. Its beneficial effects upon the participants, whose daily exercise of its principles becomes a fixed habit, cannot be overestimated, but the method of training for jiu-jitsu cannot be successfully applied to a body of men whose number runs into the millions. Science is not to be poured into a conglomerate mass of humanity. Its absorption must be a matter of individual effort. To expend the time necessary thoroughly to instruct the whole American Army would certainly be a gigantic task and its successful accomplishment inconceivable.

Mr. Mills added that large sums are now being expended to entertain the men and to supply them with apparatus for physical training and development. We are firmly convinced of the moral effect and the ultimate building and sustaining of the army morale. It is our belief that by giving

comforts, conveniences, entertainments, and provisions for physical culture to our men, in a word, ministering to their minds, bodies, and spirits, we shall accomplish something never before attempted in our armies. We expect the results to be commensurate with the great sacrifices involved. Thousands of business men have practically abandoned large interests, with more than ordinary incomes, and in many cases have left behind wives and children, volunteering to serve in this manner, realizing that because of physical or age limitations they could not be accepted in the regular army.

3. Transfusion. Experiences in Over Two Hundred Cases.—A. R. Kimpton has reached the following conclusions in regard to the value of transfusion. It is of the greatest use (1) In acute secondary anemia; that is, severe hemorrhage. For so-called "shock," uncomplicated by hemorrhage, it may be of great value, but too much has been claimed for it here. For hemorrhage of new-born babies, transfusion is specific and the use of the longitudinal sinus, as advised by Helmholz, is one of the most valuable advances of surgical technic; the tube is filled through the needle and emptied into the longitudinal sinus through the needle. For hemophilia transfusion is specific for the attack. (2) In chronic secondary anemia, when it is frequently of great value. It is of no value in acute sepsis. In acute primary anemia, such as acute leukemia, it is of no value. In chronic primary anemia, such as pernicious anemia, it is of value, but only temporarily and for variable length of time. For pernicious anemia it is the most efficient method of treatment known. Transfusion alone offers as much for pernicious anemia as splenectomy with or without transfusion, and carries none of the dangers of splenectomy. It usually brings about a remission by crisis, whereas other remissions come about usually by lysis; that is, slowly. Kimpton has found that reaction rarely follows transfusion of whole undiluted blood. Reactions are very common after transfusion of citrated blood. Massive transfusions of citrated blood may be dangerous, for whereas the percentage may be low the total quantity of citrate in massive transfusions may be considerable. Wassermanns, especially of donor's blood, should be done when time allows. Iso-agglutination tests should always be done, preferably in laboratory, between fresh bloods, as stock sera may deteriorate. Blood tests, in the author's opinion, are not necessary for new-born babies, as bloods are not usually grouped until the child is about two years old. Reactions are more likely to follow repeated transfusions, especially after four or five have been done, whether with the same or different donor. Kimpton believes that in cases where it is impossible to make blood tests—for instance, at the front—transfusion should be done without these tests.

5. The Differential Blood Count. The Arneth Formula and Doehle's Inclusion Bodies in Pulmonary Tuberculosis (With One Chart).—Rowland W. Bachman and B. H. Lucke made a study of fifty cases of pulmonary tuberculosis in order (1) to study the differential white blood count in the various stages of tuberculous patients of varying ages; (2) to study the Arneth formula of these patients; (3) to ascertain whether Doehle's leucocytic inclusion bodies are present; (4) to compare the results obtained and to give, if possible, any relation between these results and the clinical picture. The average age of the patients was 32.5 years, the majority being between 30 and 50 years of age. The authors reached the following conclusions: (1) In pulmonary tuberculosis decided alteration in the differential blood picture is found. (2) The more advanced the disease the higher is the percentage of polymorphonuclear neutrophils, and the lower the percentage of lymphocytes. (3) In cases tending to recovery the percentage of lymphocytes increases. (4) The Arneth formula shows that in pulmonary tuberculosis a large number of immature leucocytes occur in the bloodstream. (5) The more advanced the disease the higher is the Arneth's index. (6) Arneth's index shows in a general way the progress of the disease. (7) Doehle's inclusion bodies are present in pulmonary tuberculosis, especially in advanced cases.

8. The Military, Industrial and Public Health Features of Narcotic Addiction.—Charles F. Stokes points out the importance of considering from every angle all possible sources of man power at this time. Throughout the country are hordes of drug users of military age, of whom in certain sections 90 per cent. are heroin addicts. A careful study of this type of drug addict has shown that a large proportion are capable of complete mental and physical rehabilitation, provided effective measures are employed, and could be enrolled in the military services or the war industries. In the opinion of the author the problem of drug addiction is one that unattached physicians might study and thus render a patriotic service. In any organized effort to meet this situation it must be remembered that in cases of prolonged use of opium and its narcotic derivatives we are dealing with chronic depression of nervous functions, and that this depression involves the ductless glands and other organs that have to do with depression, with consequent disturbance of nutrition and possibly subsidiary intoxications. The sharp withdrawal of the drug brings about a back-sway, or counterfeet stimulation, and results in an intense crisis in the

vegetative nervous system. If this emotional outburst can be avoided, convalescence is hastened and the patient saved much intense suffering. No scheme of procedure can be satisfactorily carried out until we have federal control of the distribution of narcotics, hospital facilities for the care of women addicts, licensing of physicians qualified to treat addiction, supervision over sanatoriums, and above all the abolition of heroin. A collecting station should be established in or near each great center where addicts might be referred by the draft boards, go voluntarily, or be sent by court procedure. Here they could be classified and studied and when ready for transfer pass to the zone of disposition, prepared for assignment, each case on its merits. Stokes concludes with a note on the work done in New York City, where it was clearly demonstrated that drug addicts could be controlled by enlightened methods of discipline and administration, on an open farm without guards, and with the employment of few punitive measures. It was found that the longer the patients remained in the colony the closer they approached the normal. He points out that it is of the greatest importance that such cases should be kept away from former pals and old surroundings; and this is particularly true of adolescent heroinists.

2. Hunterian Lecture on Wolff's Law of Bone Transformation.—Arthur Keith points out that though Julius Wolff, in his great Atlas-Monograph entitled "The Law of Bone Transformation," first gave definite expression to the idea that bone in its external form and internal structure changes with every alteration of function—in brief, that a bone has the power of adapting itself to the burden it has to bear—the substance of this law is to be found in Charles Bell's "Illustrations of Paley's Natural Theology," written in 1834. Nor was Wolff's realization of living bone as a plastic tissue altogether new, a similar conception having been held by Flourens and by Hunter, but he was the first to devote years of constant work and observation to prove that the shape and structure of growing bone and adult bones depend on the strains and stresses to which they are subjected. In 1867 Cullmann, upon examining von Meyer's drawing of the femoral neck, made the discovery that its architecture was a perfect mathematical design for the transference of weight. Wolff continued his researches and, in 1870, commenced to formulate his law of bone transformation, to which he added item upon item until 1885, when it reached its final form: "Every change in the form and the function of a bone or of their function alone, is followed by certain definite changes in their internal architecture, and equally definite secondary alterations in their external conformation, in accordance with mathematical laws," or, in the simple words of the late John B. Murphy, "The amount of growth in a bone depends upon the need for it." Wolff believed that knock-knee or genu valgum was the result of faulty posture, the lines of pressure thereby being deflected from the normal. Keith, however, takes the view that in all static deformities the transformation of bone is the direct result of defective or unbalanced muscular action. The form of treatment advocated by Wolff—Macewens osteotomy of the femur, or, preferably, the exertion of pressure through the application of splints or bandages—had previously been in use. He, how-

ever, was the first to point out the extensive changes which take place in the internal architecture of the femur, tibia, and fibula after rectification. Keith shows the importance of the osteoblasts in building up the structure of bone, a fact which Wolff failed to realize. In 1852 Goodsir's investigations on a Spitzberg sponge led to the discovery of the cells or scleroblasts, which form its skeleton of spicules. The study of the scleroblasts was taken up by Minchin, and has been continued by one of his pupils, W. Woodland, who has worked on the *Sycon coronata*, a sponge that grows in shallow tidal waters, or is planted on rocks and exposed to the action of falling waves. It is studded with calcareous spicules, and is of a cylindrical shape, tapering to its attached base, and also to its oscular extremity. The required support and protection to the sponge wall are supplied by a skeleton of separate calcareous spicules. The spicule builders—the scleroblasts—are endowed with the same properties as osteoblasts, namely, the powers of fashioning and depositing the elements of the skeleton so that the sponge can best resist the forces to which it is habitually exposed. Woodland found that the scleroblast which was to give rise to the needle-shaped or monaxon type of spicule moved inwards from the dermal layer of cells to a position in the sponge wall. It then divided, and a calcareous spicule commenced to form—to be secreted—within the cell substance. As the spicule grew in length the daughter scleroblasts separated, each moving towards opposite ends of the spicule. The scleroblasts were applied to only one side of the spicule, which kept growing in length until its outer end projected into the dermal layer. The outer scleroblast then forsook the spicule and moved within the sponge wall, and shortly afterwards, accompanied by its companion, disappeared. These spicules were evidently intended as much for protection as support. Woodland also observed that triradiate and quadriradiate spicules were formed by groups of scleroblasts which arranged themselves, as Goodsir had observed, at points of a geometrical scheme, and that if the position of the sponge were altered the scleroblasts reacted in such a way as to straighten the side on which the chief stresses then fell. It is to be supposed that these cells are sensitive to certain forces—the pressures and tensions caused by moving waters and also to the force of gravity. From Dendy's work it is evident that these scleroblasts are so sensitive to vibration that they are able to discover the points of least vibration on any given spicule. Since they change their mode of building as stresses change, it is apparent that the inherited powers of the scleroblasts can be changed by the circumstances under which they work. These observations on spicule building are of the greatest importance in the interpretation of Wolff's law, which is simply this: "Osteoblasts at all times build and unbuild, according to the stresses to which they are subjected." Every orthopedic surgeon should cultivate a close observance of the behavior of osteoblasts, which by the manipulation of forces brought to bear upon them can be made to build as we will. Acute inflammation increases their activity and destroys their sensitiveness to pressures. The study of diseased conditions brings out other qualities and throws sidelights on the complex nature of osteoblasts.

3. On the Influence of Muscular Exercise on Longevity.—Sir Herman Weber points out the power of muscular exercise to increase the length of life. Walking is the most natural of all muscular exercises, as shown

by Hippocrates, and is particularly beneficial when accompanied by deep breathing and exercise of the arms. Weber sums up the effects of such exercise as follows: (1) Increased afflux of blood to the muscle with each contraction. (2) Increased nutrition of the muscle, combined with improved metabolism and production of body heat. (3) Increase of exchange of fluid between blood and tissues. (4) Facilitation of the removal of waste products. (5) Preservation of the elasticity of the thorax and lungs. (6) Abundant supply of oxygen for the blood and the metabolism. (7) Maintenance of a healthy condition of the organs of circulation, from the heart to the smallest arteries, capillaries, and lymphatics. (8) Massage of the bones, keeping up the healthy condition of the bone substance and the bone marrow, and through this the formation of a sufficiency of blood efficient for the fight with hostile bacteria entering the blood. (9) Increase of the resisting power of the body against disease. (10) Persistence of the working capacity of the brain centers, which initiate the action of the different sets of muscles. The author concludes with a reference to his own life. He attributes the satisfactory condition of health and strength which he retains in his ninety-fifth year to the exercise of the muscular system and attention to hygienic conditions, the digestive functions, mental work and the tenor of the mind, as explained in his book on "On the Means for the Prolongation of Life." He points out that both his parents died in the sixtieth year of their age.

Berliner klinische Wochenschrift.

December 31, 1917.

A Contribution to the Etiology, Clinical Aspects, and Hematology of Pernicious Anemia.—J. Zadek relates cases of saturnism, syphilis and cancer in which the hematological picture was in perfect accord with that of cryptogenetic pernicious anemia. Besides this, the writer insists upon the clinical and necropsic similarity of cases of various types of anemia. The diagnosis of pernicious anemia should be based entirely upon the hematological findings as well as upon the clinical picture, and never upon either one of these alone. Pernicious anemia following on cancer of the stomach can be attributed to an acute gastrointestinal auto-intoxication. "Essential" pernicious anemia, which for the time being is classified apart from the symptomatic anemias, examples of which are related by the writer, should draw one's attention to the possibility of a latent gastric cancer as well as to the possible presence of intestinal parasites.

The Late Effects of Absorbed Light.—Buttersack refers to three cases of solar dermatitis which did not remain localized to the exposed parts, but progressed upwards along the arms. In one instance it even extended to the calves and feet. The writer relates these facts to certain theoretical considerations in which the skin is regarded as a transformer of ray energy and to the possible part played by the internal secretions in the photodynamia of the body.

Münchener medizinische Wochenschrift.

January 1, 1918.

The Cure of Trigeminal Neuralgia with Radiotherapy.—Wilms believes that, just as in the case of sciatic, lumbar, or occipital neuralgias, that of the facial can be cured by Roentgen rays. The technique consists in applying over both temples and cheeks a penetrating dose of from 30 to 40 X, filtered through a 3 m.m. aluminum plate. The nerve is thus reached at its exit from the cranium. In neuralgias occurring in the areas of the ophthalmic and superior maxillary nerves the forehead and cheeks may be irradiated from in front. One should avoid the hair areas as much as possible, in order to avoid the destructive action of the secondary radiations on the hair. This treatment should be resorted to before intraneural injections or neurectomy have been done. The treatment is also favored by a general radiotherapeutic treatment and the exhibition of radioactive water.

The Life-Saving Effect of Blood Transfusion, Based on Eleven Cases.—H. Coenen has obtained splendid

results in eight cases of serious anemia resulting from hemorrhage by blood transfusion. The three negative cases cause the writer to offer the following conditions in order to obtain the desired results: (1) To be perfectly familiar with the technique of blood transfusion; (2) to have a proper donor; (3) the patient's wounds must not be hemorrhagic or the site of a suppurative process; and (4) to have the necessary time for carrying out the technique properly. The technique followed by Coenen consists in division of the radial artery of the donor and its suture to the median vein of the receptor. The duration of the transfusion varies to from one to two hours. The effect of the intervention, which is sometimes tardy in manifesting itself, on account of spasm of the anastomosed artery and vein, soon shows its good effects in the receptor. The color returns and the coma vanishes, and from this time on attention should be given entirely to the donor who should give the signal for ceasing the operation. This is indicated when the donor's pulse rises to 120 beats, when he becomes pale, when his respiration becomes deep and blowing, when he complains of tinnitus aurium, a feeling of weight in the limbs, and general weakness. Sudation or vomiting must not be waited for in the donor. Coenen estimates at about one litre the mean quantity of blood to be removed from the donor without causing any untoward effects.

The Value of Radiotherapy in Myomata and Metrorrhagia.—A. Lorey publishes this article in reply to that of Nagel (reviewed in THE MEDICAL RECORD) in which the latter doubted that this new method was superior to the ordinary operative treatments. Lorey maintains that it is quite exact to suppose that the effect of the rays takes place through the intermediary of the ovaries, and also that a direct action on the myoma is likewise certain. It is permissible to hope that we shall soon be in possession of a sufficiently precise technique in order to obtain a hemostatic effect without suppression of the menses in young women. The technique employed by the writer is as follows: A series of irradiations at intervals of three weeks. Each series may be given in from one to four days' duration and comprises the application of from 40 to 60 X (for each area) over two abdominal and two gluteal areas, at a distance of 30 c.m. through a 5 m.m. aluminum plate, slight compression being used. The time of exposure for each area varies from eight to twelve minutes. Lorey's results lead him to consider this procedure as far superior to operative treatment, which still has a mortality of 5 per cent. under the best circumstances.

The Sources of Contamination in Venereal Disease Among Soldiers During the War.—O. Gans gives the statistics of 1000 venereal cases. Of these there are 740 cases of gonorrhea and 260 of syphilis, figures which show a serious increase of the latter affection. Ulcers molle has been rarely encountered. The place of contamination was found to be the native town of the soldier in 38.1 per cent., the garrison town in 38.1 per cent., during leave in 12.8 per cent., the remainder having been contracted in campaigning. Disease was really contracted at the front in only 14 per cent. of the cases. The writer concludes that measures consisting in removing all suspected women from the front are insufficient, and he finally concludes that the only practical method of prophylaxis is the prophylaxis of each man in particular.

Wiener medizinische Wochenschrift.

Special Ophthalmological Number, January, 1918.

On Ocular Lesions from Air Compression Resulting from Exploding Shell.—V. Hanke estimates at 5 to 8 per cent. the percentage of ocular lesions in relation to the total number of wounds in warfare. These figures are about double those given in the statistics of former wars (1870-1904). This increase, which loses all relationship with the effective portion of the body surface represented by the eyes, viz 1/750, is due to the conditions of modern warfare and to the more general

use of explosives. Hanke reports three cases of blindness due to bursting projectiles. The lesions consisted in laceration of the posterior ciliary vessels, combined in one case with a proliferating retinitis and in another case with laceration of the choroid. The mechanism of these lesions is a sudden compression of the globe from air pressure, which in the three reported cases was sufficiently powerful to throw the men to the ground.

Ocular Wounds from Mine Explosion.—Beykovski has had twenty-one cases of ocular lesions resulting from the explosion of a mine. Among them he refers to two instances in which serious damage was produced by atmospheric pressure alone. These were cases of deep subconjunctival hemorrhage with detachment of the retina. The latter lesion might be attributed as much to the rarefaction of the atmosphere following the explosion as to the primary high pressure itself.

The Relationship of Tuberculosis to Typhoid and Dysentery.—R. von Chiari found, out of a total of 82 patients dying from tuberculosis, 15 subjects in which evidences of a former typhoid infection existed. In three cases the writer was able to detect changes of a tuberculous nature at the borders of the typhoid ulcerations. The pathogenesis of this phenomenon is clear. It simply shows that tubercle bacilli swallowed with the food became colonized on the typhoid ulcerations. The writer rejects any signification derived from Widal's reaction in such cases; it may even reach the high point of 1/100 in purely tuberculous cases and in any type of febrile state. As to dysentery, von Chiari has observed that in numerous instances it brought about death, not by itself, but from a super-added tuberculous infection. Dysentery creates an adynamic state which favors the lighting up of quiescent tuberculous processes.

Military Ophthalmia in the Austro-Hungarian Army.—A. Pichler offers a study, particularly from the historical viewpoint, on epidemics of trachoma which have developed in European armies since the days of Napoleon. The contagiousness of this affection has been greatly exaggerated. The Koch-Weeks bacillus became pathogenic only on conjunctivæ already irritated by the sun's rays, dust, etc. At present the Board of Sanitation places affected soldiers in special camps. Thus they are not withdrawn from service at the front, and can receive the necessary specialized care. Pichler has noted extraordinarily satisfactory results obtained by this means. At the end of six months a serious amelioration can already be observed in many men, and even a relative recovery may often take place.

Brazil-Medico.

January 12, 1918.

Case of Leishmaniosis Mutilans.—Machado and Aleixo of Bello Horizonte describe and illustrate the following case: The testimony of the patient was to the effect that he had first noted the presence of a pimple behind the left nostril. The lesion ulcerated and the process extended downward. No treatment was of any avail, including mercurial injections. When first seen the process had destroyed the middle portion of the upper lip, which was elsewhere markedly and symmetrically hypertrophied. The area of ulceration had involved the septum narium, although the osseous tissue was respected. The tip and alae of the nose, according to the illustrations, were also spared. The upper jaw was left exposed by the defect in the lip. The buccal cavity was extensively involved by the disease, the various tissues showing a certain degree of nodular hypertrophy. The process extending backward involved the palate, uvula, fauces, and tonsils, and the tongue was hypertrophic. The structures in the floor of the mouth are not mentioned. The process had extended to the larynx, and the epiglottis was greatly swollen, while involvement of the larynx proper was shown by the difficulty in phonation. The diagnosis was readily made by the microscope. The patient was at once placed on antimony—daily intravenous injections. Tolerance be-

ing excellent, the dose was increased until at last a violent reaction was set up. By this time the disease had been completely overcome and some plastic work was done with success. It was necessary to create a new upper lip and nostrils.

Cholelithiasis, Cancer of the Liver, Total Polyserositis, and Mitral Insufficiency.—Amaral reports this complication of diseases in a white boy of 14 years. There was a history of ankylostomiasis and ascites and of many symptoms which pointed to cholelithiasis. The liver was found to be greatly enlarged and was held to account for the ascites and perhaps for the biliary obstruction. Cancer of that organ which was the provisional diagnosis was confirmed by laparotomy. The child succumbed a few days after the intervention. Autopsy revealed the presence of double pleurisy, pericarditis, and peritonitis—which was present in addition to the mechanical element of ascites. The cancer had in all likelihood originated in the gall ducts.

February 2, 1918.

Action of Adrenaline Upon the Heart as Studied by Radioscopy.—Loeper, Dubois, and Wagner examined upon the screen the cardiac area before and one hour after the injection of 1 m.gm. of adrenaline. In all, a round 100 subjects were thus examined, including both normal and pathological material. In the majority of the normal subjects the two shadows were exactly superposed, although in certain ones there was a transitory reduction. In initial cases the enlargement of the heart was constant, while in aortic cases (aortitis, aneurysm) dilatation was also constant. Dilatation occurs soon after exhibition of the drug and will have disappeared in an average of one and a half hours. This phenomenon of dilatation is apparently passive and due to peripheral vasoconstriction. We therefore have here a good resource for determining the reserve force of the heart in organic disease. On the other hand, this dilatation need not mean organic disease, for it is also encountered in a certain number of tired, irritable, and tachycardic hearts.

Researches Into the Semeiology of Aortic Lesions as Determined by the Sphygmomanometer.—Mougeot, in charge of an army heart station, began his studies on young subjects with sound arteries as controls for three types of aortic disease—viz, auscultatory insufficiency, aortic sclerosis not involving the abdominal aorta, and finally abdominal aortitis. Several types of blowpressure apparatus were used for reciprocal control. Both the forearm and leg were used for measurements. It was learned that young, sound subjects may exhibit a relative hypertension in the lower extremities—i.e., the tension is greater than that in the upper extremities. According to the apparatus used, this may amount to from 1 to 2.5 m.m. difference. In 21 cases of aortic insufficiency the maximum pressure was much greater in the lower extremities, but varied much with the apparatus used. In 11 cases of aortic sclerosis, uncomplicated in any way, the difference in maximum pressure between the upper and lower extremities was slight. In 7 cases with abdominal aortitis the ratio between the leg and arm pressures was marked—much larger than in aortic insufficiency. In all three groups of pathological cases the minimum pressures were practically the same for upper and lower extremities. By means of these tests it was learned that certain seemingly sound soldiers had slight aortic insufficiency. Nevertheless, some excess of tension in the lower extremities must be regarded as physiological.

Another French Case of Sodoku.—Ramond and Lévi-Bruhl report the case of a French soldier who after having been bitten by a rat developed the characteristic local and general reaction of sodoku. Of interest was a certain resemblance to trench fever which led to a discussion of the possible identity between the two diseases. That is to say, "Could trench fever be sodoku conveyed otherwise than by a bite?" The trench rat, once attacked with the supposed spirillo, might in turn infect the trenches and thus indirectly convey its disease to man.—*La Presse Médicale.*

Book Reviews.

TRAINING AND REWARDS OF THE PHYSICIAN. By R. C. CABOT, M.D. Lippincott's Training Series. Price, \$1.25. Philadelphia and London: J. B. Lippincott Company, 1918.

A work of this scope is hardly subject to review in the usual sense of the term. Every beginner in medicine and every young man contemplating the adoption of this as a career should possess a copy of it. It is packed with information and contains little of a purely dogmatic character. The book has three sections: the preparation of the physician, his helps and hindrances of development, and his rewards; the latter being set down as psychic rather than material.

THE THYROID GLAND IN HEALTH AND DISEASE. By ROBERT MCCARRISON, M.D. (R. U. I.), D.Sc. (Belf.), F.R.C.P. (Lond.); *Lauréat de l'Académie de Médecine*, Paris; Major, Indian Medical Service. Price, \$4.00. New York: William Wood & Company, 1917.

MCCARRISON'S classical work on the thyroid is undoubtedly well known to most medical men, particularly those interested in the function and diseases of this gland. In the present publication the author has collated his papers of the past fourteen years into one volume, and, as he states in the preface, has drawn from the work of others to fill in where his own observations have failed to provide. The book is divided into three parts. The first deals with the Thyroid and Parathyroid glands in health; the second with the factors which cause them to depart from health; and the third with the morbid states—including goiter, cretinism, tetany, myxedema, and Graves' disease—which result from this departure. Part I is devoted to anatomy, histology, physiology, chemical physiology, functions, and life history of the thyroid and parathyroids. The function of the colloid material has long been a question of dispute and in this connection McCarrison says: "I look upon the colloid as a substance designed to contain an emergency reserve of iodine, a reserve which is not primarily called upon in the daily routine of the body demands. . . . The 'emergency ration' of iodine-containing colloid is, however, called upon when the supply of iodine in the food runs short, under the demands of excessive sympathetic excitation such as occurs in rage or fright (Cannon) at certain periods of life—dentition, puberty, menstruation, pregnancy, or lactation—as a result of residence at certain high altitudes, at certain seasons of the year, and when the body is invaded by microorganisms or subjected to certain intoxications."

Part II treats of various deleterious agencies that may affect the thyroid and parathyroids, such as malnutrition, residence in insanitary surroundings, bacterial and other toxins, infections, intestinal toxemia, the influence of consanguinity and heredity, psychic disturbances, etc. The author lays considerable stress on the influence of intestinal toxemia as a cause of thyroid abnormality, and in support of this hypothesis gives many experiments carried out on animals, and points out their application in the human subject.

Part III, which comprises fully two-thirds of the text, is concerned with diseases of the thyro-parathyroid apparatus and their treatment. It is in this part that the author is able to utilize his enormous clinical and experimental experience to the greatest advantage. Seriatim, the sections are titled as follows: Endemic goiter; congenital manifestations of goiter with experimental considerations; congenital goiter; endemic cretinism; treatment of congenital hypothyroidism and cretinism; parathyroid disease and the origin of tetany; tetany; inflammations and simple toxic goiter; myxedema; Graves' disease. A large fund of valuable information is contained in this part; no point is neglected. In the first section on endemic goiter, of which the writer saw so much in India, mention is made of treatment by intestinal antiseptics and vaccines. The author claims very gratifying results from the use of autogenous vaccines made from organisms belonging to the colon group, and also from staphylococcus vaccines. The section on Graves' disease is, in our opinion, one of the best presentations of this much discussed malady which has appeared recently. McCarrison leans strongly to the theory of gastrointestinal toxemia as the

etiological agent. He considers the question of thyroidectomy and emphasizes its limitations.

Three appendices are added. The first contains a list of the author's publications on goiter and allied subjects from 1906-1916. The second contains tables showing the influence of intestinal antiseptics on simple goiter. The third appendix gives a schedule of the more important epidemiological and experimental researches carried out by the author, and serves to show the large amount of work he has done on the subject.

The volume is printed on high-grade paper in clear, easy type, making it a delightful book to read. The illustrations are numerous and well executed; most of them are original. Taken altogether, the work forms one of the most valuable contributions to a very difficult field of medicine, and is one that will well repay reading by the specialist or general practitioner alike.

DISEASES OF WOMEN. By HARRY STURGEON CROSSEN, M.D., R.A.C.S. Associate in Gynecology, Washington University Medical School, and Associate Gynecologist to the Barnes Hospital; Gynecologist to St. Luke's Hospital, Missouri Baptist Sanitarium, and St. Louis Mullanphy Hospital; Fellow of the American Gynecological Society, and of the American Association of Obstetricians and Gynecologists. Fourth Edition, Revised and Enlarged. With 800 engravings. Price, \$7.50. St. Louis: C. V. Mosby Company, 1917.

THIS work has been reviewed already more than once, but as its scheme is based upon somewhat novel ideas, it will not be out of place to recapitulate these. It is devoted exclusively to the diagnosis and treatment of diseases of women as those diseases are met with in the office and at the bedside by the general practitioner. Other considerations are passed over, except such as are necessary to bring the work to its highest usefulness as a practical guide in the lines indicated. Since the issue of the first edition no alteration in the general scheme has been made, but a great deal of material has been added. With regard to this, the fourth edition, the two principal additions are: first, numerous drawings and photomicrographs illustrating gynecologic pathology; and, second, a chapter on the ductless glands in their relation to gynecology. The chapter on the ductless gland system was written by Dr. Hugo Ehrenfest. It may be said that owing to the fact that Dr. Harry Sturgeon Crossen has been called to active war duty as a member of the Medical Officers Reserve Corps the manuscript was completed and prepared for press by Dr. Hugo Ehrenfest, Professor of Obstetrics and Gynecology, St. Louis University. The work has been brought up to date and, in particular, the problem of the relation of the endocrine gland system to gynecology is discussed at greater length and more systematically than ever before attempted in any textbook of gynecology.

The engravings are a feature of the book. Their excellence renders the elucidation of the text an easy matter. As a book of reference for practitioners this last edition will prove as valuable as the former editions.

A COMPEND ON BACTERIOLOGY, INCLUDING PATHOGENIC PROTOZOA. By ROBERT L. PITFIELD, M.D., Pathologist to the Germantown Hospital, Late Demonstrator of Bacteriology at the Medico-Chirurgical College, Philadelphia; Visiting Physician to St. Timothy's Hospital and Chestnut Hill Hospital, Philadelphia. Third Edition. With 4 Plates and 82 Other Illustrations. Price, \$1.25. Philadelphia: P. Blakiston's Sons & Co.

WRITTEN primarily for the use of medical students, this third edition of this Compend has been brought up to date and all unnecessary old matter removed. An entire chapter has been devoted to the subject of immunity, and for so small a book an exceedingly comprehensive piece of work is offered. The illustrations in the main have been drawn from the works of well-known authors in the field of scientific medicine, and are many and wisely chosen. The chapter on filterable viruses has been the contribution of Dr. Herbert Fox of the University of Pennsylvania (Pepper Laboratory). This little work meets the requirements of the high standard always found in this set of quiz-compend.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting Held February 21, 1918.

VICE-PRESIDENT, DR. GEORGE D. STEWART, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Pediatrics.

Internationalism and Public Health.—Dr. GEORGE E. VINCENT, of the Rockefeller Foundation, made this address. He said that he was not a pediatrician, but he might, as a layman, speak on a subject of profound interest in connection with the war, namely, child welfare, not only as it related to young infants but as it affected children of school age. The war situation had not as yet made much impression on the children of America. In order that we might avoid such injury to our children as had befallen those of Belgium and other European countries we should begin now to combat anything that threatened their welfare, for whatever impaired the vigor and vitality of the nation's children struck at the basis of the nation itself. Dr. Vincent said he wished to speak more particularly of Internationalism and Public Health. Thus far we knew so little about the war in this country that we might be justified in speculating as to what might happen after the war was over. After the war was over the world would probably be patched together again just as it had been after wars in the past. At the time of the Franco-Prussian war Louis Pasteur said that after that war was over no Frenchman would ever again associate with a German, and no self-regarding German would ever again come to France. Yet before 1914 something of the kind that Pasteur said never could happen had come to pass. A German diplomat at the same time said that it was a source of great regret that it would be twenty years before he could go to Paris, thirty before he could go to London, and forty before he could again go to Vienna. However, something like amicable social relations between these countries were resumed before the lapse of many years after that war was over, so it seemed altogether probable that something like international relationships would again be established between the warring nations of the present time. It was also possible to conceive of a situation in which the relations of the allied nations would not be as harmonious as they were to-day. There would probably be a perfect orgy of explanations and justification of motives after the war was over. The most useful international gatherings when that time came would not be those dealing with politics, morals, or religion. It would be on the basis of scientific interest that the world would begin to be patched together again. After having conquered the Philippine Islands with machine guns some doctor suggested that a dispensary be established. This was done and the doctors by selecting the diseases that were amenable to treatment soon impressed the inhabitants of the island with the value of a dispensary. The doctor then brought with him his friend the school master. After a time the dispensary developed into a floating hospital, which covered a circuit of some fifteen stations in the Sulu Archipelago. It was equipped with a thoroughly modern operating room. There was also a base hospital to which this ship might carry patients when this seemed desirable. Such a plan of subduing and protecting a backward people might be found useful elsewhere, and it might prove a more rational method of subduing such a people than machine guns. If one went into the Southern States he would find that there were some 600 people engaged in the problem of controlling hookworm disease. This was a perfectly understood disease and therefore something worth while clinging to as an illustration of what public health work meant and what it could accomplish. In this disease one got perfectly definite and demonstrable results so that it was effective in teaching the value of public health work. The Government gave its support until the value of the work had been demonstrated and then it withdrew and left the local health organizations to carry on the work. During the past year model sanitary codes drawn up by the International Health Board of the Rockefeller Foundation had been adopted

by Ceylon and Guatemala. Dr. Vincent said that he referred to these things in order that his hearers might see that public health activities played a definite part in the progress of civilization. It meant a great deal to have 600 men go out from this country to establish sanitary organizations, men who went as ambassadors of friendliness and beneficence to mankind. While this was not a spectacular method of advancing civilization there was no doubt that it played an important part in building up the structure of internationalism, and it might be depended upon to help in bringing the world together again.

A few years ago several professors in Chicago thought it would be a good idea to see what could be done toward introducing occidentalism into the Orient. They decided that the most practical way of attacking the problem was to send a couple of professors into the East to study conditions on the ground. For this purpose a professor of geology, with his planetary theories, and a professor of theology, not a modern theologian from an eastern center of learning, but a plain Middle West theologian, were chosen and sent to China. Difficult as it was to get a unanimous report on any subject from any group of men, it was even more unusual that a geologist and a theologian should agree, yet those men after their investigation sent in a unanimous report stating that if occidentalism and orientalisms were to meet and fuse it would not be on a basis of politics, philosophy, or religion, but that a basis for such a union might be found in modern science. This did not make an appeal as being a warm, human, and throbbing plane upon which to effect a union, so a committee was appointed to go to China and make a further investigation. The report which this committee submitted recommended the establishment of scientific relations with the East, and especially scientific relations as applied to human welfare. As a result two medical colleges were planned for China. The cornerstone of the first was laid in Peking last September by Dr. Frank Billings of Chicago. The building was now under process of construction and represented all that was modern in equipment for scientific work, but the architecture of the buildings was Chinese. Instead of an arrogant, intrusive, occidental structure, the exterior would be perfectly merged into the beauty of the Chinese city and would represent nothing aggressive or interpolating from without. Inside, however, it represented all that was signified by modern medical science. The medical college planned for Shanghai was not to be built until after the war. Arrangements were made whereby the pre-medical course would be provided by the College of China in Peking. In the central part of China existing educational institutions had been subsidized and grants given them to enable them to provide the standard pre-medical education. These schools would form the tributaries of the new medical colleges. The hospitals in China would be so standardized that internships would be provided for the graduates of the medical schools. One might suppose this system extended. Great Britain might deem it wise to establish a medical school in Calcutta such as the United States had established in China. She might establish another medical center in Cairo, and possibly events might so shape themselves that such a medical center might be planted in Constantinople. A world system would thus be developed. If one medical center had a professor with a message for the medical world he might be detached from his institution and sent to Shanghai, Calcutta, Cairo, or Constantinople, and medical men all over the world coming to these centers would come into contact with him. In this way new medical knowledge could quickly be placed at the service of the entire world. Arrangements could also be made for an exchange of medical students. There were at the present time 57 medical students from foreign countries studying in this country. Medical missionaries were now given but one year in seven in which they could come home to study, but with the completion of such a system of medical centers it would be possible for them to study for a time each year.

There was at the present time a Franco-American Committee which planned for the exchange of scholarships so that there was at least a beginning of an international system of student migration as well as

a beginning of the exchange of professors. Under a well developed exchange system a cablegram sent to a medical center, say for a pathologist, would be met by an immediate response. The pathologist would be sent where he was needed and at the same time some one would be sent to the center from which the pathologist had gone to be trained to take his place later on and to release him. There was no question that the operation of such a system would have a direct bearing on international relationships. There was nothing more creditable in modern times than the fact that the initiative in preventive medicine had been taken by the members of the medical profession. There were some people who denied this altruism on the part of the medical profession because they could not comprehend it; they could not conceive of men doing a thing whereby they were endangering their own means of livelihood. It was not to be expected that the work done in preventive medicine would meet with full appreciation. They would have to derive their satisfaction from a consciousness of rectitude and of duty well performed.

Thus far there was really no successful system of devoting full time to public health work. In only a few places had solid achievement been attained in the training of public health officers. Such courses in public health work as were offered by some of our medical colleges left much to be desired. However, a school had been established in connection with Johns Hopkins University which would be opened next September. This school would afford a complete training for public health work. Dr. William H. Welch had severed his connection with Johns Hopkins University and had become the director of this new institution. The work done in this institution would be done not only in the laboratory and the lecture room, but in the field. Actual health surveys were to be made in a section of Baltimore set apart for this purpose. This school was to have its own corps of instructors, its own curriculum, and its own professional spirit. It would not be difficult to gain admission to this institution, but it would be difficult to win a diploma. That this work would have an influence on internationalism there could be no doubt.

In speaking of the tuberculosis work in France, Dr. Vincent recalled that in 1915-1916 it was found that the tuberculosis situation in France was serious, and Dr. Hermann M. Biggs was sent to study the conditions and to suggest means of dealing with the situation. He recommended the training of doctors and nurses to carry on a campaign in France similar to that which had been successful in the United States. Dr. Livingston Farrand, with a staff of assistants, went to France to assist in solving the problem. He did not herald his arrival in France with highly colored newspaper articles stating that he had arrived in France and that now all would be well. It was to be remembered that it took a high degree of spirituality to be continually exposed to charity and to accept the situation amicably. One French woman expressed this feeling by saying that the French were exposed to two enemies, the Germans and their own friends, the Americans. Dr. Farrand performed his work quietly and unobtrusively, in the closest co-operation with public spirited French people. He assisted in organizing for anti-tuberculosis work one of the arondissements in Paris and one of the departments outside of Paris, thus demonstrating the method of carrying on a campaign against tuberculosis in both a city and a rural community. Motor cars with a traveling exhibit, such as we were accustomed to employing in this country, had been placed in operation. Seventy nurses were being trained to go into this work. The method of co-operation between the American and French Red Cross organizations served as an illustration of international co-operation, yet this represented but one agency.

There was another agency for the promotion of internationalism in the Surgical Research Council. This set up workers in London, Paris, and Washington, and provision was made by the governments for constant intercommunication between these groups. They formed what was in reality a syndicate. This meant a recognition of the community of interest in science. This was the spirit that would be valuable in bringing the

world together again. Dr. Vincent expressed the conviction that the work done by medical men for the public health and in research, in the exchange of professors, in the migration of students, and in application of science to human welfare, a work which recognized the community of mankind and laid emphasis on the things that men had in common, science that sought the truth and applied it for the benefit of mankind, would knit the old world together again. He said that he did not paint a picture of the millenium as about to arrive, but he did believe that we were drawing closer together and that the things that were being accomplished in public health work by quiet persistence and good will would create an understanding among different peoples, and that it would be found that nothing was more effective in reconstructing the world than preventive medicine applied to the welfare of mankind.

Dr. GEORGE D. STEWART expressed the gratitude of the audience to Dr. Vincent for having presented the broad view of the drawing together of different peoples. This broad view was most enlightening to the members of the medical profession who were accustomed to having their attention concentrated on a very narrow field. All America was being unified under the forces that were at work to-day. Every man between the ages of twenty-one and thirty-one was getting a physical examination and all the doctors were getting additional medical education. The war was giving us a big nationality to fit a great nation. It was to be hoped that we would have, not necessarily universal military service, but universal service for our country and our fellow men.

Child Welfare Work in France by the American Red Cross.—Dr. ESTHER LOVEJOY presented moving picture films, shown for the first time in this country, demonstrating the relief work done by the Red Cross among the refugees from the occupied territory of France and Belgium. She said she had been interested in Dr. Vincent's remarks about conquering the Filipinos with machine guns, and could not help wondering why we had not employed the dispensary first before using the machine guns. In regard to America doing relief work in France, it had been her experience that the general feeling among the French was not that of the woman who felt that the French people were besieged by two enemies. On the contrary, there was a feeling of confidence and joy that the Americans were there in France. The French people might read in the papers that the Americans were helping them, but they liked to see the visible evidence of a helping hand in the shape of an American uniform or even an American in citizen's clothing. The visible evidence that we were assisting these people was an inspiration to them. Dr. Lovejoy said she had heard Dr. Farrand speak for a few minutes to a French audience. He spoke in French and they were very much interested in what he had to say. In fact, the French people were greatly interested in anything that was American. The pictures shown illustrated the relief work done at Evian and Toul. All the people sent back from the occupied territory of France and Belgium were either old people or children of from two to fourteen years of age. Women with more than one child were sent back to France, but those having but one child were kept because they could still do some work and care for one child. Of those sent back 40 or 50 per cent. were children under fourteen years of age. There were few children under two years of age because most children that age were fathered by Germans and were kept in Germany. The children sent back home were mostly undersized and undernourished. If a child appeared to be fairly well nourished it was the rule to find that it was two or three years older than one would think from its size and appearance. The people coming to Evian were sent from the occupied territory of Belgium or France by a three days' journey through Belgium. From three hundred to three hundred and fifty thousand refugees had been sent back in this way since the beginning of the war. The old people presented a most pathetic picture, for it was much harder to get them to leave their homes than it was the younger generation. They seemed to be attached to the locality in which they lived more than to the people about them, and would cling to their homes even in the midst of bursting

shells. The pictures showed Dr. William Palmer Lucas and Dr. Woods Hutchinson at work among the refugees as they were being taken from the trains. Evian was a town of only 5,000 inhabitants, and the convoys brought in about 300 refugees every day. These had to be evacuated as rapidly as possible in order to prevent congestion. Dr. Lovejoy described how the spirit of France has been kept alive among the boys being brought in from the occupied territory. The younger children, however, remembered nothing but war and were apathetic, apprehensive, and fearful. At Evian an isolation hospital was maintained by the Red Cross to prevent the introduction of contagious diseases into France. They also operated a large delousing plant which cared for 200 persons at one time. Many of the children brought back had not been washed for months, and as a consequence skin diseases were rife among them. The necessity that compelled children to wear gas masks inflicted the greatest cruelty upon them. Dr. Lovejoy exhibited a gas mask such as the children in the occupied territory wore and showed how uncomfortable they made a child. The biggest work the Red Cross was doing to-day was backing the French societies in the relief work they were undertaking.

A MEETING FOR THE SAFE-GUARDING OF CHILDREN IN WAR TIME.

Held at the Hotel McAlpin, New York, February 25, 1918.

DR. S. JOSEPHINE BAKER IN THE CHAIR.

THIS meeting was held under the auspices of the Pediatric Section of the New Academy of Medicine, the Bronx County Medical Society, the Brooklyn Pediatric Society, the Bureau of Child Hygiene of the New York City Department of Health, the Babies' Welfare Association, the Civitas Club, the Women's City Club, the National Association of Great Britain and Ireland for the Study and Prevention of Infant Mortality, the Women's National Health Association of Ireland, and the Women's Municipal League.

DR. S. JOSEPHINE BAKER, in opening the meeting, said that no two things seemed more dissimilar than children and war, and it was exceedingly difficult to realize how close the connection between them was. The most important thing to be done after looking to the welfare of our fighting men was to look to our second line of defense, the children. Practically all the child welfare work now being done throughout the world was because of war. The large number of men rejected as unfit for military service at the time of the Boer war directed attention to the need of better physical development among young men of the British Empire and means were sought whereby the physical defects that unfitted them for military service might be overcome or prevented. In France child welfare work assumed a place of importance because of the falling birth rate. Germany and Austro-Hungary also reported a declining birth rate. All of these countries were making much more extensive efforts than ever before toward the preservation of child life. In the beginning of the war all the attention of the people was directed to providing for the fighting forces, but after a year or two of war Europe awoke to the fact that the infant mortality rate was increasing and that many children were suffering from undernutrition. Although we had not as yet had to face the problem of a declining birth-rate, it was probable that we would have to confront this problem if the war continued. It was a fundamental fact known to every student of public health that the baby was the first to react to whatever economic conditions obtained in a community. Thus far the effect of the war upon children in this country was due to economic causes. There were today in New York City 216,000 children suffering from undernourishment because of the increased price of food and the lack of certain types of food essential to the proper nutrition of children. To meet this situation before it became more acute the Federal Children's Bureau would present a program. There were immediate problems which must be met at once throughout the United States. One of the deficiencies to be met was the lack of proper birth registration in a number of States. The United

States still had a baby mortality which was practically criminal. To be effective, child welfare work must be done by groups of people working in their own communities. The importance of this work was evident when we stopped to consider that the children of today would be the men and women of tomorrow who must do the reconstruction work after the war was over. Therefore we must get together early and work as we had never done before to fit the children to perform the great task that lay before them. Once in a generation we found a person who did a particular thing so superlatively well that he gained recognition for all time. We had with us this evening, Dr. Baker said, such a man, Dr. Truby King, who had reduced the infant mortality rate of New Zealand from 80 per 1,000 living births to 50 per 1,000 living births. He was responsible for the lowest infant mortality rate in the world today. Dr. King was on his way to England for the purpose of organizing the child welfare work in Great Britain.

Child Welfare Work in New Zealand.—DR. TRUBY KING of New Zealand made this address, which he illustrated with lantern slides. He said that the simplest way to present the subject was to tell briefly how they had come to make a beginning and what they were now doing. The chief factor that had brought their attention to the necessity for child welfare work was the lamentable inefficiency of the men who were examined for military service. The large number of disabilities and defects which unfitted the men for military service were preventable so that this state of affairs practically amounted to criminal negligence. The main cause for the existence of these defects was the unpreparedness of the women for motherhood and the vast amount of bottle feeding which was responsible for poor jaws, poor teeth, and all forms of indigestion, respiratory troubles, etc. There were several factors that played a prominent part in the reduction of the infant death rate in New Zealand. Their work was not the result of any new discovery; it was founded on the principles laid down by Professor Rotch and Harvard and Dr. Holt of this city. All they had done was to put into practice the principles known in America and in the Old World. What they had done was to adapt this knowledge to their own conditions. Some two or three years after having had the need of infant welfare work brought to his attention Dr. King said he happened to spend a year in Japan. There the population was largely agricultural. Most of the people lived on small farms and the women helped to do the work of the farm. They were well developed, lived in the open air, wore loose clothing, and all nursed their children. History told of the military efficiency of the Japanese. In his own Island Dr. King said his work had been the management of a colony for mental diseases and in connection with this he had the administration of a large farm. This involved the study of the best methods of agriculture and of stock raising. By applying scientific methods to his farming he had been able to achieve amazing results. They had found that by adding a certain substance to the soil they were able to double the crop of potatoes. By the application of scientific methods to storage they had been able to protect their crop from loss. They learned that a transplanted oak did not do as well as one allowed to continue its growth where it began to grow. Transplanting the tree cut the roots and interfered with nutrition. The same was true of children. The artificially fed infant was a parallel instance; the roots were cut so far as proper nutrition was concerned. Taking the cows they found that they had been losing 20 per cent. of their calves from "scouring," or, in other words, from infantile diarrhea. They found that by the application of scientific methods to the rearing of the calf a difference of 100 pounds in weight resulted by the end of the sixth month. After they had applied scientific methods to the care of their calves they no longer lost them by "scouring," they no longer had tuberculosis, and the cows never gave any more trouble even though they lived to be twenty years old. The way in which a calf was fed made all the difference in the world in the shoe that was made from its hide. Since scientific methods worked out so well in their crops and their live stock it seemed worth while trying them with children. In initiating a campaign for child wel-

fare, attention was first paid to the known requirements of mothers and their infants. That it was evident that the basic principles of nursery hygiene must be taught, just the ordinary kind of information which for generations had been handed down from mother to daughter. Their first step was to secure a nurse who should go about among mothers giving this instruction. After they had a nurse doing this work for about six months the wives of the doctors began to realize the value of the instruction and availed themselves of it. It was not long before the women began to recognize the value of this instruction and a women's committee offered to relieve the speaker of some of the responsibility. Gradually these women's committees were organized throughout the country, until at the present time there were 80 of them among a population of about one and a quarter million. The women composing these committees represented all grades and classes of society and all varieties of religious persuasion. In demonstrating the value of scientific methods applied to the rearing of children, liberal use was made of the illustrations drawn from the farm and the dairy. Articles were published in all the weekly papers on the feeding and care of the baby and this had been continued up to the present time. In addition a number of pamphlets were published and widely distributed, courses of lectures were given, and a hospital was established for the training of nurses in infant welfare work. This work was at first supported through voluntary contributions. The Government was, however, not slow to recognize the value of the work and gradually extended its assistance. For every dollar now contributed by private agencies the Government gave five or six dollars. It furnished free transportation for the nurses and in many ways lent its support and encouragement without in any way taking away the initiative from the women's committees. The work had been taken up very wholeheartedly by Lord and Lady Plunkett. They had a large family and Lady Plunkett came to the school to learn the scientific methods there taught. She became greatly interested and was very successful with her family. She lost no opportunity of telling what the knowledge we had given her had done for her family. She explained that if this knowledge was useful to her it would be useful to others. Women of social position, the wives of professional men, and others of the more intelligent classes, had come to them for instruction and the knowledge then filtered down through all classes of society; if one worked with the submerged classes only the knowledge would not become disseminated so readily.

In New Zealand they had another advantage in their work, and that was their equable climate, a climate very much like that of California. However, he did not think that a more rigorous climate with greater variations in temperature, such as we had in the United States, was necessarily an impediment to the attainment of as great a reduction in the infant mortality as they had obtained, for the colder and more stimulating climate produced a more vigorous race, just as the Scandinavians were more vigorous as a race than the Italians. All the factors which had aided them in their work in New Zealand were not evolved hastily within the background of the war; they had been a long time in developing, had grown slowly and deliberately and from the more intelligent classes of society had worked downward. The question might be raised whether it was right to give this knowledge to people who were able to pay for it. His answer was "Yes." We recognized the necessity of providing public schools, high schools, and universities for all, so why not this knowledge which was more essential to human welfare than any other. The question might also be asked whether giving this knowledge to the people was acceptable to the medical profession. It was well known that the medical profession had always worked for the advancement of preventive medicine, even though it cut the ground from under its own feet. The medical profession had always been ready to sacrifice itself for the sake of a healthier population. Dr. King showed slides giving the death rates of the large cities of the world. Auckland led with a death rate of from 8 in 1900 to three and a fraction in 1914. New Zealand as a whole had a death rate of 5.1 when New York had one of 13. The spirit of competition had also played a part in

stimulating the women to take better care of themselves and their babies.

Dr. King then referred to his study of mental diseases and the means of their prevention and said that only one-third of the people who went into an insane asylum ever came out again, and most of these never really adapted themselves to a normal life again. The only way to diminish insanity was to begin in the cradle. The only way to stop all vice and crime and disease was to begin in the cradle. He showed slides illustrating the changes in the brain cells in certain forms of insanity. When brain cells were damaged by such poisons as alcohol or syphilis they lost their arborizations and degenerated into masses of fatty tissue; the individual with such brain cells vegetated for a time and then passed out. That alcohol and syphilis were poisons causing such results one could make people understand, but the thing they had not understood was that equally dangerous poisons were generated in the systems of all of us. In order to have a healthy organism the lungs and kidneys must functionate properly and dispose of the poisons generated in the body. If in addition to a sluggish function of the kidneys and lungs there was sluggishness of the bowels, we had a condition in which poisons were produced and absorbed into the blood that had a more deleterious effect on the cells of the body than the poisons of alcohol and syphilis. The only way to restore the cells of the body when they were thus damaged was by proper bathing, exercise, fresh air, and plain food; if these did not restore the cells of the body, nothing could do so. It was these poisons in the blood of the mother that caused her to suffer from neuralgia, headache, lassitude, etc., and they unfitted her to be the mother of a healthy child. When women understood these things and gave proper attention to bathing, exercise, proper clothing, and proper food, and in addition learned how to care for their babies, we would not have an infant death rate of 50 per 1,000 living births, but a rate of 25 deaths per 1,000 living births would be considered abnormal. The most rapid period of growth was during the prenatal life and the next most rapid period in the entire life of the individual was during the first two years of life. This was the time *par excellence* for the growth of the brain and nervous system. By the time a child was three or four years of age its brain had attained a growth comparable to that of the remainder of the body at the age of twenty-one years. The physical and mental capacity of the individual for his entire life was determined for him during the first few years of life. A child's teeth were determined for him before he was born by the condition of the mother's blood. The importance of plenty of cool fresh air could not be overestimated. The mother should have this before and after the birth of the child. Mother and child should have separate beds so arranged that a current of fresh air passed between them continually.

Dr. King exhibited pictures of the hospital where, he said, they did not keep babies any longer than was necessary, but they kept and trained nurses and mothers. The babies were placed in homes as soon as possible. They had a separate home for the mothers and made it as attractive as they could. They frequently had mothers come and stay for a time because they were failing to nurse a baby satisfactorily. They had frequently been able to restore a mother's milk supply after it had been absent several weeks. In this home the mothers were taught the relative values of the different varieties of foodstuffs and how to cook. They were also instructed in regard to what constituted proper clothing, and a fashion injurious to health was held up to unsparing ridicule. They especially condemned the high heeled shoe. They had also been teaching schoolgirls the care of the baby. They first tried it in the hospital with the sick babies, but concluded that sick and ailing babies were not best calculated to instill a love of motherhood, so now they were keeping a few normal babies to aid them in giving this instruction to the schoolgirl. Another point which Dr. King emphasized was the importance of plain food and of food that required chewing. He said that if we would have a virile and vigorous race we must turn back to simpler and more primitive ways of living. We must live more in the open air and we must cease to live on "pap" foods and to feed our children on

sweets. In New Zealand they had many open-air schools and had demonstrated that the children in these schools developed greater physical strength and mental alertness than those who studied indoors. In old Rome when one wished to express contempt for the ignorance of a man it was said, "He knows neither letters nor swimming." Swimming was then held to be an essential part of a liberal education. There was not a more stimulating form of exercise than swimming, and it should be made a part of the education of every child. There should be a swimming pool in connection with every school. If everyone were accustomed to taking a swim, a rub down, and twenty minutes of active exercise daily the amount of inefficiency in the world would be greatly reduced. By due attention to the matters of hygiene mentioned, even a delicate woman might become healthy and the mother of vigorous children; on the other hand, even a strong woman could not disregard the laws of hygiene and expect to be the mother of healthy children. In New Zealand this essential knowledge was considered not unworthy the attention of women of rank. The world to-day was concerned about its falling birth rate; men and women were shirking the responsibilities of parenthood. In New Zealand men and women were proud of their fatherhood and their motherhood.

Dr. BAKER said that if she had any message from the city it was to thank Dr. King for the inspiration he had brought. They were more determined than ever that New York should not long take second place to New Zealand. To come back to the war, we had done much work, but much more remained to be done. Between 40 and 50 per cent. of our drafted men were rejected because of physical defects. It was not possible to permit conditions that produced such results to continue. The Federal Child's Bureau had a plan to present which was designed to promote child welfare and prevent these defects in the next generation.

The Plans for the Children's Year; One Hundred Thousand Children Must Be Saved in America During the Second Year of Our War.—Dr. JESSIE PEIXOTTO of the Federal Children's Bureau, in presenting the plan of the Bureau, said that war asked of every person a feeling of patriotism. It asked of some that they go to the front. Others of us stayed at home with nothing to do but to sit and wait. As a result of what had been planned at Washington those of us who hitherto had had nothing to do but sit and wait would have work to perform. In the proposed campaign there were four main features. These were: (1) The protection of infants and mothers. (2) The protection of mothers with older children, children approaching adolescence, where the mother was confronted with the problem of providing for such children on an insufficient income, and also with many other problems and perplexities that arose as the child approached adolescence. (3) They were going to concern themselves with the children sent to work before they should be sent. (4) They were going to take up the question of providing decent and sufficient recreation for adolescent children. In view of the fact that the Women's Council on National Defense was already organized it had seemed wise to work through that organization rather than to make a new departure. The necessity of saving children for the future was evident to all of us. More children should be well born than ever before and, having been well born, they wanted them to live. The drive was to begin on April 6, and their slogan was, "Save 100,000 babies to the nation." Many States would complain because they thought their assignment of babies to be saved was unjust, but that was because of the lack of proper birth registration. The Federal Bureau had called upon the women's committees of the Council on National Defense to organize for the work, and at the present time there were 5,090 such committees organized and ready for work. In cities in which the women's committees were very large they had asked them to divide into subcommittees, each subcommittee taking a different branch of the work, and then coordinating their work. They had asked for volunteers to help in the clinics and infant welfare stations. Physicians had been invited to give information with reference to conditions that were responsible for a high infant mortality and to make suggestions for their correction. They hoped to get many nurses

and doctors who would volunteer to work from twelve to twenty hours a week. The local committees were going to study the economic side of the question and make suggestions whereby people of limited means might meet the high cost of living. At Washington they could only dream the dream and sound the trumpet; it was for the committees in their own home towns to make the dream a reality and to do a work that was only second to fighting in the front line trenches.

The first step in the campaign would be the weighing and measuring of babies. From time to time the other features of the program would be announced.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

THE NATIONAL BOARD OF MEDICAL EXAMINERS.

Chicago, October 10-18, 1917.

(Concluded from page 485.)

SURGERY.

1. Give symptoms, prognosis and treatment of abscess of the brain.
2. Give diagnosis and differential diagnosis of carcinoma of the lip.
3. Give diagnosis, differential diagnosis and treatment of chronic cystic mastitis.
4. Give diagnosis, differential diagnosis and treatment of strangulated inguinal hernia.
5. Give diagnosis, prognosis and treatment of fracture of upper third of femur.
6. Give diagnosis, differential diagnosis and treatment of stone in the bladder.

OBSTETRICS AND GYNECOLOGY.

1. Describe briefly the changes that take place in the fecundated ovum up to the time that segmentation is complete.
2. Discuss pernicious vomiting in pregnancy. (a) Etiology; (b) Symptoms, including urinary findings; (c) Treatment.
3. Describe the clinical history, mechanism of labor and the treatment of a face presentation, left mento-anterior position.
4. Discuss the pathogenesis, symptoms and differential diagnosis of acute pyelitis complicating pregnancy.
5. Bacteriology, symptoms and treatment of puerperal sepsis.
6. Causes, ordinary complications and treatment of proclitica uteri.
7. Causes, symptoms and treatment of chronic endocervicitis.
8. Causes, symptoms and treatment of vesicovaginal fistula.
9. Clinical history, diagnosis and treatment of purulent pelvic inflammation.
10. Diagnosis, prognosis and treatment of coexisting uterine fibroids and pregnancy.

ANSWERS.

SURGERY.

1. ABSCESS OF THE BRAIN. *Symptoms:* "The symptoms in traumatic cases are acute, and, as there is usually diffuse meningitis, there is intense pain, fever, and rigors, coma quickly supervening. In the more common chronic cases the symptoms are often vague in the early stages, but when well marked consist in signs of intracranial pressure. 1. The headache and tenderness are severe and localized to the site of the abscess. 2. The temperature is subnormal, unless there is associated meningitis. 3. The pulse is markedly slowed, even down to 30 or 40. 4. The patient is quite intelligent, but cerebation is very slow; vomiting and optic neuritis are usually present. 5. Motor symptoms may occur if the abscess is in the anterior part of the temporo-sphenoidal lobe, either irritative or paralytic. If the cerebellum is affected, there is giddiness both while walking and lying down, together with weakness

of the hand-grip and increase in the knee-jerk on the side affected. Lateral nystagmus often occurs.

"Treatment: The abscess must be opened as soon as possible. Unfortunately, many cases are only diagnosable when it is too late for evacuation to produce a cure. As cerebellar abscess is more common, it is as well to explore the cerebellum first, unless focal symptoms point to the temporo-sphenoidal lobe as the site. A flap is turned down and a piece of bone removed with a trephine. The dura is then incised and the abscess punctured with a trocar and cannula or sinus forceps. These should be passed in various directions till the pus is found, and then the opening must be enlarged, the pus gently washed out, and a drain left in for several days. For a temporo-sphenoidal abscess the trephine opening should be made $\frac{3}{4}$ inch above the posterior root of the zygoma, and directly above the posterior border of the bony meatus; for a cerebellar abscess, $1\frac{1}{2}$ inches behind the center of the external auditory meatus and 1 inch below Reid's base line. In most cases the mastoid antrum should be first explored; by removing the bone behind it the lateral sinus can be exposed, and by working above or below it the cerebrium and cerebellum can be explored." (*Aids to Surgery*.)

Prognosis: Abscess of the brain is a very serious condition, but it is amenable to surgical treatment if this is carried out thoroughly and promptly. Occasionally, a temporo-sphenoidal abscess may burst and the pus escape through the middle ear.

2. Carcinoma of the lip usually occurs on the lower lip, most often in men. It may appear as a wart with an indurated base or as an ulcer involving the whole thickness of the lip and having indurated base and edges; there is no necrotic sloughing floor as in chancre or gumma. The submaxillary and submental lymph glands are enlarged.

Chancre occurs as an ulcer with steep and indurated edges, the process is limited but involves the thickness of the lip at the vermilion border; the lymph glands on the same side are involved, the induration is less than in cancer, and the secondary symptoms of syphilis soon appear. As a rule, it appears earlier in life than cancer, and either lip may be affected.

3. Chronic cystic mastitis occurs usually in patients at or past the menopause. There is infiltration and overgrowth of the connective tissue, and proliferation of the epithelium, so that the acini are filled. Cysts may form owing to the pressure of the interstitial growth preventing the escape of secretion. These are known as involution cysts, and the fluid may be clear or turbid and brown. As a rule these cysts are multiple, scattered and tiny, but one may become large and resemble a tumor. **Symptoms:** There may or may not be pain in the breast, but a number of small scattered lumps are usually found. Both breasts are usually affected. The skin is seldom attached over the lumps, but the lymphatic glands may be slightly enlarged. Distinct cysts may be felt in some cases. The disease slowly progresses, and ends in atrophy of the breast or general cystic formation. It is said that cancer is like-

ly to follow interstitial mastitis. The **diagnosis** from scirrhus rests on the fact (1) that the whole breast, and probably the other breast, are affected with scattered nodules; (2) that the nodules are free from the skin and pectoral fascia; (3) that the lumps are less distinctly felt with the flat of the hand than those of scirrhus; (4) that the glands are not so stony hard as are those of scirrhus. The two diseases are occasionally present together, and in any case of doubt an exploratory incision and microscopic examination should be made. **Treatment** consists in supporting the breast and applying a belladonna plaster. Single cysts should be removed, but if the whole gland is cystic complete removal is better.—(*Aids to Surgery*.)

4. Symptoms of strangulated and inguinal hernia:

General.—"Severe pain comes on suddenly after some effort, at first referred to the umbilicus, and subsequently to the site of the hernia. This is accompanied by some shock. The pulse is weak, and, though slow at first, becomes rapid; the skin is cold and clammy; vomiting occurs, and soon becomes frequent and fecal smelling. Constipation is complete, though both feces and flatus may be passed at first from the lower bowel. The patient generally becomes exhausted from the vomiting and inability to take food. When gangrene occurs the temperature becomes subnormal, the pulse very rapid and weak, and the patient dies of toxemia from the general peritonitis which follows gangrene. **Local.**—A tumor forms at the site of the hernia, or more often the patient has been the subject of a hernia, which he now finds to be irreducible, tense, tender, and without impulse on coughing. If allowed to persist the sac and coverings become gangrenous."

Treatment is taxis or operation. "Operative treatment should be undertaken at once when gentle taxis has failed. An incision is made over the sac, which is then opened. There is usually fluid in the sac, so there is no danger of wounding the gut. The fluid is washed away, then the cause of strangulation is made out, and a hernia knife guided up to it by a finger or broad hernia director. The constriction is nicked in one or two places and the gut is drawn down so that the site of strangulation may be examined. Omentum is ligatured and removed. If the patient is profoundly collapsed and will not bear a prolonged operation, an artificial anus is established by dividing the constriction outside the sac, so as not to open the peritoneal cavity. The loop of bowel is then opened to give free exit to the feces. Most of the cases which have to be treated in this way are so bad before treatment is commenced that a fatal termination must be expected. If the patient can possibly stand it, immediate resection gives the best chance, and with Murphy's button or a bobbin much time can be saved. A radical cure is advisable after the strangulation has been relieved, unless the patient's condition contraindicates it. Liquid food is given at the end of twenty-four hours, and the bowels need not be disturbed for five or six days, when castor oil may be given."—(*Aids to Surgery*.)

The following table of differential diagnosis is given by Eisendrath:

	REDUCIBLE HERNIA.	SIMPLE IRREDUCIBLE HERNIA	STRANGULATED PARTIAL ENTEROCLE	STRANGULATED COMPLETE HERNIA.	INFLAMED HERNIA.	OBSTRUCTED OR INCARCERATED HERNIA.
Swelling ...	In hernial region.	In hernial region.	Usually none to be felt.	Larger than before and firmer.	Larger than before.	Larger than before.
Impulse	Distinct on coughing.	Distinct on coughing.	None	None.	Present on coughing.	Present on coughing, but less marked.
Reducibility.	Disappears on lying down or manipulation.	Does not disappear after same tests.	Irreducible.	Irreducible.	Generally reducible, but may not be.	Irreducible.
Other local signs	Soft if intestine, firmer if omentum.	Usually feels firm and doughy.	Some pain over hernial region.	Dull pain over swelling, later signs of peritonitis.	Redness, pain, local heat.	
Signs of obstruction..	None.	None.	Not as marked as in complete form. May pass liquid feces and gas; vomiting not so marked.	Colicky pains, absolute constipation; vomiting; later fecal.	But little nausea. No absolute constipation.	Gradual onset; vomiting slight; bowels can be moved. Occurs in aged.
General disturbances..	None.	None.	Not as early as in complete.	Marked and early intoxication.	Fever and leukocytosis.	Slight, no collapse.

5. "In fracture of the upper third of the femur, the symptoms are pain, swelling, muscular spasm, abnormal mobility, crepitus, deformity, and shortening. The upper fragment is pulled forward by the iliopsoas, and drawn outward and rotated externally by the external rotators; the lower fragment is pulled upwards by the flexors and extensors of the leg, inward by the adductor muscles, and rolled outwards by the weight of the limb. The treatment is flexion of the thigh and traction to reduce the deformity, and the application of a double-inclined plane with extension in the axis of the thigh. A shot bag may be placed over the upper fragment if it is too short to be retained by an anterior splint. The Hodggen splint can be used; it consists of two long pieces of wire joined at each extremity and at the middle by a cross piece. The limb rests in a trough of flannel attached to the frame. A Buck's extension is applied and attached to the foot piece, and further extension made by suspending the limb by cords, passing obliquely upwards to a vertical post at the foot of the bed. All forms of treatment, however, are unsatisfactory, and if the displacement is marked and the patient young and healthy, operative fixation should be considered."—(Stewart's *Surgery*.)

6. The symptoms of stone in the bladder are: Increased frequency of micturition; pain at end of urination, chiefly felt at the end of the penis or in the neck of the bladder; the urine may contain pus, mucus or blood; a "click" can be obtained by using a searcher or sound; examination by the cystoscope may reveal the presence of the stone. Actual diagnosis is made by the use of the sound and the cystoscope. The treatment consists in removing the calculus, by litholapaxy, or lithotripsy, or lithotomy (suprapubic or perineal).

OBSTETRICS AND GYNECOLOGY.

1. *Changes in the ovum following impregnation:* "Directly after the formation of the nucleus of segmentation by the fusion of male and female pronucleus the ovum begins to segment. The original mass divides itself into two cells (blastomeres), these into four, and so on until the whole ovum is surrounded by a layer of cells including a group of somewhat larger cells morula, or mulberry mass), and a hollow cavity containing albuminous fluid. This stage of development is called the blastula, or blastodermic vesicle. The cells of the ovum next arrange themselves into a thinned-out, laminated layer around the periphery of the ovum, and another layer just within this, the offspring of the central mass of cells (the ectoderm), and the proliferating central mass itself, the entoderm. Regarding the surface of the ovum, an oval, opaque region may be observed (the embryonal area), and in the middle of this area a streak of greater opacity appears—in the primitive streak. At the site of this streak a depression next appears—the primitive groove. A microscopic examination of a section through this region now shows the development of a median layer of cells (the mesoderm), made up of cells derived in part from a layer furnished by the ectoderm and by another furnished by the entoderm. In the course of its development the mesoderm develops lateral reduplications and parts into two layers (the parietal and visceral layers) inclosing spaces—the body-cavity, or celom. The parietal or somatic layer unites with the ectoderm to form the somatopleure. The visceral or splanchnic layer joins the entoderm to form the splanchnopleure. At the end of the second week the development of the embryo proper begins, by the formation of the neural folds, the neural canal, the chorda dorsalis, or notochord, and the somites, or provertebræ."—(Hirst's *Obstetrics*.)

2. *Pernicious vomiting in pregnancy. Etiology:* It may arise from a variety of causes. The most common are: Reflex disturbance, caused by the rapid growth and distension of the uterus; some pathological condition of the uterus or its adnexa; some pathological condition of the gastrointestinal tract; excessive sexual intercourse; kidney insufficiency, or some other form of faulty nitrogenous metabolism. The principal symptom is continuous vomiting, which results in exhaustion and death unless relieved. The urinary examination shows diminution of urine and total nitrogen; ammonia is in excess, indoxyl and skatoxyl are increased. Leucine, tyrosine, albumin and sugar may be found. The

treatment consists in rest in bed in a quiet, darkened room and the administration of easily digested foods, such as milk, broths, eggs, etc. A careful search must be made for some local exciting cause, and if any such condition is found it should receive appropriate treatment. Sexual intercourse should be interdicted. The bowels should be kept freely open. Sodium bromide, camphor, cocaine, silver nitrate, cerium oxalate, hyoscine hydrobromide, antipyrine, etc., are among the drugs used internally. Rectal alimentation may be necessary, and, as a last resort, dilatation of the cervix and internal os, or abortion may be performed.

3. *Mechanism of labor with a left mento-anterior position:* "The successive steps are: Extension.—The head presents at the superior strait imperfectly extended, so that every case of face presentation may be said to begin as a brow presentation. There is also at first imperfect engagement of the presenting part, on account of the large diameters presented at the superior strait. Under the influence of the expulsive action of the uterus and the resistance of the pelvic walls, the brow, caught upon the pelvic brim, is held stationary, while the chin descends lower and lower by an extreme extension of the head. Molding, or an accommodation of the shape of the presenting part to the shape of pelvis, occurs to a moderate degree or not at all, because the face is a loose fit in the normal pelvis. The molding is confined to the back of the skull. Lateral inclination is a constant feature, so that one cheek is a little deeper in the pelvic canal than the other one. Descent of the presenting part follows the dilatation of the cervical canal, the descent of the chin being accomplished almost solely by the extension of the head, and not by a descent of the head as a whole. Anterior rotation of the chin occurs as soon as it encounters the resistance of the pelvic floor. Anterior rotation is followed by the engagement of the chin under the symphysis pubis. Then follows the delivery of the head by flexion and propulsion, the mouth, nose, eyes, and forehead sweeping over the perineum and appearing successively at the posterior commissure. Restitution and external rotation follow the escape of the head from the same causes that impose those movements upon the head in a vertex presentation. The delivery of the body takes place as in a vertex presentation."—(Hirst's *Obstetrics*.) *Management:* Expectant treatment may suffice; but care must be taken to observe that the chin does not rotate backward. Spontaneous version may occur and the presentation become a vertex one. Failing this, or as a means of favoring this, postural treatment, such as Walcher's position, has been recommended. If, in spite of this, engagement has not occurred, cephalic version is indicated, care being taken not to rupture the membranes. If this is not successful, podalic version should be tried. If, after all these manipulations, the child is still alive and the head is engaged, symphyseotomy is indicated; if the child is dead, craniotomy should be performed.

4. *Pyelitis complicating pregnancy:* "This is an infection of the bladder, ureter, and kidney separately or together by the bacillus coli communis. The infection has been supposed to come from the blood or to be an ascending one from the external genitals. Berry Hart believes that it is an infection from the large intestine *via* the extra-peritoneal wall of the bowel and general connective tissue, where there has been stasis of intestinal contents from ineffective evacuation of the bowel. The weak points in the abdomen where structure is a compromise sufficient for ordinary use only, are the pelvic floor, the inguinal and femoral regions, and the extra-peritoneal surfaces of the large intestine, bladder, ureter, and kidney. Into these last areas the bacilli pass from the bowel, travel, and entering the ureter or bladder set up the pyelitic condition. According to some, stagnation of the urine in the ureter, owing to the pressure of the uterus, is a factor. The right ureter is more often affected. The symptoms may come on from the fourth month onwards, and are lateral abdominal pains over the kidney and ureter region or in the appendix region. They thus cover a wide area. Vaginally the bladder may be tender, and there may be pain on pressure over the ureter where it lies in the bladder wall. The patient has a chill with a rise of temperature in the evening (103° to 104° F.), and with a remission to nearly normal or even below it in the

morning. The pulse rate is increased, but not markedly. *Differential diagnosis.* This condition must be separated from appendicitis, lower inflammatory thoracic conditions, acute intestinal obstruction, and eclamptic prealbuminuric conditions. What keeps one right, as a rule, is the examination of the urine, the rigor, and the kidney tenderness. The distension, sometimes extensive, may be puzzling, but it is to be noted that it has been observed in pyelitis by good observers apart from intestinal obstruction or appendicitis. It is often set down as an albuminuria of pregnancy, as we have albumin in the urine, headache, sickness, but here again the more careful noting of the acid re-action, the presence of the bacillus coli and its cultivation, should lead us in the right direction." (Berry Hart's *Guide to Midwifery*).

5. **PUERPERAL SEPSIS.** The bacteria which cause puerperal sepsis are: *Streptococcus pyogenes*, *staphylococcus pyogenes aureus*, *gonococcus*, *bacillus coli communis*, *bacillus diphtheriae*, *bacillus typhosus*. They are generally introduced by the fingers of the physician or nurse, or by instruments, or general lack of cleanliness. *Symptoms:* Chill; rapid rise in temperature, to about 103° or 104° F., higher in the evening than in the morning; sweats; rapid pulse; depression; dry tongue; anorexia; carphologia; scanty, high-colored, albuminous urine; restlessness; sometimes delirium or coma. The uterus is large, and tender; the lochia are diminished or suppressed; the milk secretion is often suppressed; pain in the abdomen; peritonitis may develop. *Treatment:* Prophylaxis is of the greatest importance. Purgatives; vaginal douches; some recommend curettage, others decry it; the introduction of antiseptics into the uterus; supportive and general treatment are indicated; specific sera and vaccines have been recommended by some.

"The treatment of puerperal sepsis is both local and general. Locally a thorough disinfection of the whole genital canal is called for in every case. It may appear unnecessary, and may prove, on actual experience, to be even harmful, but no one can tell beforehand how necessary this procedure is. In the vast majority of cases it is productive of the greatest good. It is only occasionally useless, and very rarely actually harmful. It should precede all other treatment for puerperal infection. The method of disinfecting the genital canal may be described as follows: A double tenaculum, a large, dull curette, a placental forceps, and an intrauterine catheter are boiled for fifteen minutes. The operator disinfects his hands and arms and wears sterile gloves. The patient is placed in the dorsal posture across the bed, with her buttocks resting on a rubber pad. The external genitalia and the vagina are scrubbed with tincture of green soap and pledgets of cotton; the vagina is doused with a sublimate solution, 1:2000. The operator then seizes the anterior lip of the cervix with a tenaculum. An intrauterine douche of sterile water, at least a quart, is administered. Then, with the placental forceps, and, if necessary, with a dull curette, the uterine walls are gone over thoroughly but lightly in all directions, six to twelve times, until nothing is brought away but bright blood. A second intrauterine douche concludes the treatment. If the womb is flabby and large, with a tendency to flexion, so that the drainage of the uterine cavity is not good, it is advisable to pack it with iodoform or sterile gauze. In addition to cleansing the uterine cavity, false membranes or areas of inflammation and localized infection on the cervix or vagina should be treated by the application of a solution of nitrate of silver, a dram to the ounce. It may be necessary to repeat the intrauterine douches several times—in fact, several times a day for many days: in this case plain sterile water only should be used. The general treatment is stimulating. The patient should have as much food of an easily digestible character, chiefly milk, as she can assimilate, and as much alcohol as she can consume without showing the physiological effects of it. Digitalis is useful as long as the pulse is above 110. Strychnine may be combined with it in suitable cases. To tide the patient over emergencies, carbonate of ammonium in large doses, by the bowel, and nitroglycerine, hypodermatically, may be required. Inhalations of oxygen may be of service. Absolute rest and freedom from all disturbances, mental and physical, must be insisted upon, and the patient

should be given the best nursing that the family can afford." (Hirst's *Obstetrics*.)

6. **PROCIDENTIA UTERI.** *Etiology:* Injury at childbirth, lacerated perineum, relaxation and elongation of the ligaments of the uterus, loss of rigidity of the abdominal walls, increase in the weight of the uterus, subinvolution, increased intraabdominal pressure. *Symptoms:* The patient complains of a feeling of "bearing down"; of trouble with micturition and defecation; of pain and fatigue on walking, and of "falling of the womb." The cervix is low down in the vagina; the sound shows that the uterine cavity is lengthened. Procidentia is evident on inspection. *Treatment:* "A prolapsed uterus must first be placed in proper position, or a procidentia reduced. In many cases the introduction of a rubber ring pessary will then suffice to prevent recurrence. But it will often be found necessary to repair a torn perineum, removing at the same time redundant portions of the vaginal walls, before the ring will remain in the vagina. When such an operation is contraindicated, and the vaginal orifice is so wide that a ring cannot be kept in, some form of pessary with a vaginal stem and perineal bands will be required. In cases of procidentia, where the exposed surface is much ulcerated, the patient should be kept in bed, emollient applications made to the ulcers, and vaginal douches given. When the ulcers have healed, a pessary may be introduced. Procidentia due to supravaginal elongation of the cervix must be differently dealt with. Amputation of a portion of the cervix must therefore form the first step in the treatment, and it may be required also when the hyperplasia is secondary to descent. Cases of prolapse and procidentia which resist milder measures require further operative procedures, such as ventrofixation of the uterus or the shortening of the round ligaments. It is in cases of this kind that hysteropexy has often given satisfactory results. Total extirpation of the uterus has been advised and practised for the treatment of procidentia."—(Sutton and Giles' *Diseases of Women*.)

7. **CHRONIC ENDOCERVICITIS.** *Causes:* Puerperal lacerations of the cervix, foreign bodies, tumors, polypi, excessive coitus, bacteria (especially gonococci). *Symptoms:* These may be slight or severe; headache, backache, pain in the pelvis, disordered menstruation, digestive disturbances, sterility, are the most important. *Treatment:* Removal or alleviation of the cause, cleanliness and disinfectants; palliative treatment is of little avail and a thorough excision of the affected area, followed by a plastic covering of the exposed surfaces, (such as Schroeder's operation) is the best method of treatment.

8. **VESICOVAGINAL FISTULA.** *Causes:* Sloughing of the vagina during protracted labor, injuries from obstetric implements, ulceration due to pessaries and other foreign bodies, ulceration of the bladder, and vesical calculi; carcinoma of cervix, vagina or rectum. *Symptoms:* "The patient complains that she cannot hold her urine. Some urine may collect in the bladder and be voided periodically if the fistula is small; otherwise the urine escapes from the vagina as rapidly as it enters the bladder. The vulva and vagina are inflamed and excoriated by the constant wetting, and sometimes a phosphatic incrustation forms." *Treatment:* "The principles underlying the treatment of all fistulae of mucous canals apply here, namely: (1) The vivifying of the edges of the fistula; (2) the careful suturing of the edges; (3) immediate union. (1) Access to the vagina is obtained by means of a duckbill speculum held by an assistant. The margins of the fistula pared by means of a sharp, delicate knife mounted on a long handle. These knives are usually supplied in sets of three or four, with the blades adjusted at different angles to meet any difficulty according to the position of the fistula. In paring the edges care is taken to avoid bruising, but it is necessary to thoroughly vivify the whole circumference of the fistula. (2) The sutures may consist of silk thread or silkworm gut. Whatever material is used it should be introduced with a slender needle, and should traverse the muscular but not the mucous coat of the bladder or urethra. This stage affords much scope for ingenuity on the part of the operator. After the sutures are fastened it is wise to test the wound to ascertain if it be watertight. For this purpose milk is injected into the bladder. Should any

escape through the wound an additional suture is inserted at the situation of the leak. If all be secure the bladder and vagina are gently irrigated with warm water and the patient returned to bed."—(Sutton and Giles' *Diseases of Women*.)
